The Cochrane collaboration undertook a systematic review, reported in 2015, to assess the effectiveness and safety of any CAM in the management of acne vulgaris. This included 35 studies, with a total of 3,227 participants in parallel-group randomized controlled trials (or the first phase data of randomized cross-over trials) of any kind of CAM, compared with no treatment, placebo, or other active therapies, in people with a diagnosis of acne vulgaris. The primary outcome was improvement of clinical signs assessed through skin lesion counts. Some evidence from single studies showed low-glycemic-load diet, tea tree oil, and pollen bee venom (PBV) may have an effect reducing total skin lesion counts and acne severity scores. However, small sample sizes and poor methodological quality limited the strength of the evidence. Evidence from other existing randomized controlled trials does not support the use of herbal medicine, acupuncture, or wet-cupping therapy for the treatment of acne vulgaris. The evidence for a secondary outcome (number of participants with remission) for herbal medicine versus antibiotic was uncertain. Two trials reported QOL showed the benefit of herbal medicine compared with western drugs. From the review of 31 studies, the Cochrane review cautioned there is a lack of evidence to support the use of other CAMs, such as aloe vera, copaiba essential oil, dried fruit of *Berberis vulgaris*, or seaweed oligosaccharides for the treatment of this condition. Most studies were done in a traditional Chinese medicine context; therefore, results might be less generalizable to western medicine. The review highlights potential adverse effects from herbal medicine (dizziness, dry mouth, nausea, diarrhea, or stomach upset); acupuncture (pain, itchiness, or redness); and tea tree oil gel (pruritus, dryness, burning sensations, and skin flaking).[73]

A 2018 review focused on the use of essential oils and aromatherapy in acne, examining existing evidence from small pilot studies.[74] It reaffirmed there is only weak clinical evidence that tea tree oil 5% may be used as an alternative acne therapy. Several agents may be helpful as complementary therapy due to biologic plausibility, including lactobacillus-fermented *Chamaecyparis obtuse*, copaiba, sandalwood oil, rosemary extract, jeju essential oil, and Korean citrus, but concluded there is little supportive clinical evidence.

The use of botanical preparations that are nonstandardized should be discouraged in favor of traditional quality-controlled preparations that have evidence of efficacy. The lack of appropriate data, absence of quality assessment, and inconsistencies in search methodology suggest that CAM cannot be recommended for acne therapy now.

Glycolic Acid

Another agent considered alternative therapy for acne vulgaris is glycolic acid. The efficacy and tolerability of a 0.1% retinaldehyde/6% glycolic acid combination (Diacneal) has been evaluated for mild-to-moderate acne vulgaris.[75] Physician and patient ratings of acne symptom severity and tolerance performed at baseline and months 1, 2, and 3 showed mean numbers of papules, pustules, and comedones were significantly reduced from month 1 on, demonstrating that glycolic acid is effective and well tolerated in mild-to-moderate acne vulgaris.

Both glycolic acid–based, salicylic acid or salicylic acid derivative–based (eg, lipohydroxyacid), and amino fruit acid–peeling preparations have been used in the treatment of acne. There is very little evidence from clinical trials published in peer-reviewed literature supporting the efficacy of peeling regimens.[62] Topical corneolytics, including retinaldehyde/glycolic acid or lactic acid, induce a comedolytic effect and may also facilitate skin absorption of topical drugs.[58] Further research on the use of peeling in the treatment of acne needs to be conducted to establish best practices for this modality.

Hydroquinone

To control pigmentation, hydroquinone, which reversibly damages melanocytes, has been used as a hypopigmenting agent in concentrations of 2% to 4%, in preparations of clear or tinted gels, which are more drying, and as vanishing or opaque, flesh-tinted creams, with or without α-hydroxy acids or sunscreens. Hydroquinone causes fading of epidermal but not dermal pigmentation. Onset of response is usually 3 to 4 weeks, and the depigmentation lasts for 2 to 6 months but is reversible. While effective in the removal of melanin, hydroquinone has been clinically found to be a possible carcinogen and causes a blue-black discoloration known as ochronosis.[76]

After considering new data and information on the safety of hydroquinone, the FDA issued a proposed ruling in 2006 about hydroquinone products. The FDA proposed reversing earlier rules that hydroquinone is generally recognized as safe and effective. The FDA has not yet issued a final ruling on the status of nonprescription hydroquinone, and many physicians consider a ban unnecessary, given the lack of convincing evidence of carcinogenic risk to humans and the rarity of ochronosis occurrence.

Treatment of Scarring

Drug and nondrug measures for scar resolution are important in acne vulgaris because many patients are scarred despite adequate treatment and scarring carries an emotional toll. Interventions for atrophic scars might be aided through early identification of patients at risk using a risk assessment tool for scar development. One such tool incorporates four factors: worst ever severity of acne, duration of acne, family history of atrophic acne scars, and lesion manipulation behaviors.[77]

Effective procedures for treatment of scarring focus on resurfacing techniques. For patients with mild scarring, nonprescription α-hydroxy acids may be used, while severe scarring may be corrected with other treatment modalities that require consultation with a dermatologist. Dermabrasion, local or subcuticular excision, collagen implants, chemical peels (eg, 70% glycolic acid, trichloroacetic acid), and laser therapy have been used to improve scarring. Atrophic scars can be treated with laser resurfacing. Usually the scar is not completely removed, but a more cosmetically acceptable result is achieved. Keloids and hypertrophic scars can be treated with intralesional triamcinolone, cryotherapy, topical steroids, and silicone sheeting. Surgical options for scars include excision, augmentation with collagen or fat, chemical peels, subcision, and injection of autologous fibroblasts.

Special Populations

About 20% of young infants (2-3 months of age) develop papules, pustules, and less commonly closed or open comedones, primarily on the cheeks, due to placental transfer of maternal androgens (neonatal acne). The acne subsides within a few months with regular maturation. Boys are affected more often than girls because of a transient increase in testosterone secretion during the third and fourth month of intrauterine life. *Malassezia* spp. may be involved in pathogenesis.[31] Resolution occurs without therapy.[78] Infants with neonatal acne may have more severe teenage acne.[31]

The treatment of acne in children is similar to treatment for adults. Because topical therapies may be more irritating in children, initiation with low concentrations is preferred. Systemic treatments should be reserved for more extensive cases. Erythromycin is preferred over tetracyclines for children younger than 9 years of age because tetracyclines can affect growing cartilage and teeth.

Although treatment with isotretinoin has numerous potential minor adverse effects in patients of all ages, an uncommon complication in young patients is premature epiphyseal closure. This generally occurs when isotretinoin is administered in high doses, thus limiting long-term therapy.

There is a growing population of women seeking acne therapy and a clinical perception that acne in women requires systemic treatment. Analyses of clinical trials have shown that topical therapy can be efficacious in this group. Most patients have an acne presentation similar to adolescent acne, with mixed inflammatory and noninflammatory lesions on multiple facial areas (not limited to the mandibular area). Topical therapy with a retinoid and antimicrobial can be a good option. Data support the use of retinoids, including adapalene/benzoyl peroxide in both 0.1% and 0.3% concentrations, tretinoin 0.04%, and a retinaldehyde 0.1%/glycolic acid/6% cream. Among antimicrobial agents, both dapsone and clindamycin/benzoyl peroxide have efficacy if a topical retinoid is added. Azelaic acid 15% gel has also shown good results in a small study. Hormonal therapy, including oral contraceptives (OCs), can play an important role in management of acne in women and is typically used in combination with topical acne therapy.[67]

Selecting appropriate treatment in pregnant women can be challenging because many acne therapies are teratogenic; all topical and especially oral retinoids should be avoided. Oral therapies, such as tetracyclines and antiandrogens, are also contraindicated in pregnancy. Topical and oral treatment with erythromycin may be considered.

Acne in skin of color is an increasing problem, presenting unique challenges. Postinflammatory hyperpigmentation (PIH), a hypermelanotic reaction to skin inflammation, is a common occurrence in patients with acne, particularly in those with darker skin and those who excoriate their lesions, affecting all genders and ages. It has a prolonged duration and can be more bothersome than active acne lesions. Prevention (including sun protection) and early treatment of underlying acne-associated inflammation effectively is a primary approach to PIH management. Chemical peels, lasers, and other light therapies may also be used for PIH; however, these methods can also cause pigmentation problems so should be used with care. Topical retinoids also improve pigmentation by inhibiting melanosome transfer to keratinocytes and increasing epidermal turnover, lessening pigmentation. It is important for the patient to be aware that many PIH lesions resolve spontaneously, but slowly.[67]

A variety of topical agents have studies that specifically included patients with skin of color, confirming their safe use in this population. These include all the currently available topical retinoids, benzoyl peroxide, azelaic acid, clindamycin, dapsone, and clascoterone. A key goal of therapy in this population is to minimize postinflammatory hyperpigmentation from irritating topical agents, with an emphasis on use of hydrating cleansers and non-comedogenic moisturizers.[79]

Another important counseling point is to emphasize sun protective measures to minimize the darkening effects of UV irradiation on post inflammatory hyperpigmentation. Recommendations include use of a broad-spectrum sunscreen, protective clothing, and inclusion of vitamin D–rich foods or supplementation.[76]

Drug Class Information

This section reviews the pharmacology and mechanisms as related to pathophysiology for pharmacologic options recommended in the guidelines for mild, moderate, and severe acne. It will also review evidence of efficacy and safety as well as kinetics, interactions, dosing, and administration when relevant.

Topical Therapies

Topical therapy agents are available over the counter or by prescription. The choice of therapy can be influenced by age of the patient, site of involvement, extent and severity of disease, and patient preference. Topical therapies may be used as monotherapy, in combination with other topical agents, or in combination with oral agents in both initial control and maintenance. Strength of recommendations for treatment of acne with topical therapies is shown in Table 117-2.

TABLE 117-2

Monitoring of Medications Used in Acne Treatment and Maintenance Therapy

Medications	Adverse Drug Effects	Monitoring Parameters	Comments
Exfoliants			
Resorcinol	Irritant and sensitizer	Degree and/or changes in signs or symptoms of irritancy (redness, discomfort, peeling, skin breakdown, or dermatitis)	Should not be applied to large areas of the skin or on broken skin
Sulfur	Avoid eye contact—slight ophthalmic and skin irritation	Degree and/or changes in signs or symptoms of irritancy (redness, discomfort, peeling, skin breakdown, or dermatitis). Discontinue use if excessive irritation	

		results	
Salicylic acid	Mild irritant—burning and reddening, local skin peeling	Degree and/or changes in signs or symptoms of irritancy (redness, discomfort, peeling, skin breakdown, or dermatitis)	Begin with a low concentration and increase as tolerance develops Not a sensitizer
Retinoids			
Isotretinoin	Side effects: mucocutaneous (most common), musculoskeletal, and ophthalmic systems Common: dryness of mucus membranes (lips, mouth, eyes, nose) dry skin, itching, hair loss, thirst, back pain, myalgia, headaches, and central nervous system effects Increased cholesterol Teratogenic Sun sensitivity Depression and suicide—controversial	Test for pregnancy twice before starting Contraceptive measures must be started 1 month prior, continued during the 2 months of treatment and for at least 1 month after stopping treatment (but normally 4 months) Laboratory monitoring during therapy should include triglycerides, cholesterol, transaminases, and complete blood counts (before, during, and after treatment) Degree and/or changes in signs or symptoms of irritancy to skin (redness, discomfort, peeling, skin breakdown, or dermatitis) Degree and/or changes in signs or symptoms of irritancy to mucous membranes (mouth, nose, eyes) Instances of headache or central nervous system symptoms Note prior psychiatric symptoms, monitor patients at each visit for early recognition of changes in mood or psychological well-being (before, during, and after treatment)	Drying agents must be discontinued Sun-avoidance strategies and sunscreen use recommended Vitamin A supplementation Use moisturizers (lip balm, nasal moisturizers, eye lubricants, temporary removal of contacts) Most adverse effects, such as cheilitis, and dry nose, eyes and mouth, are temporary and resolve after the drug is discontinued Advise patients about a possible risk of depression and suicidal behavior
Tretinoin/retinoic acid	Common: erythema, dryness, burning, photosensitization Rare: true contact allergy. Use cautiously in pregnancy (Irritation: tazarotene > retinoic acid > adapalene)	Degree and/or changes in signs or symptoms of irritancy to skin (redness, discomfort, peeling, skin breakdown, or dermatitis) Skin changes in areas of sun exposure—dermatitis or hives	Additive effects with concomitant topical drying medications, such as products with high concentrations of alcohol, astringents, or abrasive soaps Gels and creams are less irritating than solutions Sun-avoidance strategies and sunscreen use recommended
Adapalene	Side effects include erythema,	Degree and/or changes in signs or	Less photosensitivity than other

	xerosis, burning and desquamation Less irritation than other retinoids Photoirritation or sensitization	symptoms of irritancy to skin (redness, discomfort, peeling, skin breakdown, or dermatitis) Skin changes in areas of sun exposure—dermatitis or hives	agents Sun-avoidance strategies and sunscreen use recommended
Tazarotene	Side effects include irritation, erythema, xerosis, burning, and desquamation	Skin changes in areas of sun exposure—dermatitis or hives	Contraindicated in pregnancy due to the large surface area Short contact therapy, 1-5 minutes every other night, gradually increasing to overnight advocated for dosing in patients with sensitive skin Oily complexions may tolerate twice daily, short contact time
Topical Antimicrobial Agents			
Benzoyl peroxide	Dryness and peeling appear after a few days, erythema, burning, pruritus Rare reports of contact allergic dermatitis May bleach hair and clothing Body odor, odor on clothes and bedsheets Irritation is concentration dependent—most frequent with 10% gel Irritation from gels used as vehicles—water-based < alcohol = acetone	Once tolerance is achieved, the strength may be increased to 5% or the base changed to the acetone or alcohol gels, or to paste Degree and/or changes in signs or symptoms of irritancy to skin (redness, discomfort, peeling, skin breakdown, or dermatitis) Hives	Increased skin irritation or drying effect with other medications, soaps, and cosmetics with strong drying effect Chemically incompatible with retinoic acid Cross-reactions with other sensitizers, such as Peruvian balsam, cinnamon, and other benzoic acid derivatives (topical anesthetics)
Clindamycin	Erythema, peeling, itching, dryness, and burning	Signs or symptoms of irritancy to skin (redness, discomfort, peeling, skin breakdown, or dermatitis)	
Oral Antibiotics			
Erythromycin	Gastrointestinal upset (nausea, vomiting, diarrhea) Vaginal candidiasis	If gastrointestinal adverse effects occur, monitor hydration Vaginal discharge	Drug interactions: Inhibits CYP1A2 and CYP3A4: carbamazepine, cyclosporine, theophylline, and warfarin Safe in pregnant women and children
Tetracyclines	Gastrointestinal intolerance: (tetracycline > erythromycin >	Vaginal discharge Skin changes in areas of sun exposure	Contraindicated in pregnant women or in children younger

	doxycycline = minocycline) Vaginal candidiasis Photosensitivity is dose-dependent (doxycycline > tetracycline)	—dermatitis or hives	than 9 years of age Absorption decreased by food, chelated by antacids and milk To be taken on an empty stomach
Minocycline	Drug-induced lupus Pigment changes in skin, mucous membranes, and teeth Hepatitis Urticaria Dose-related dizziness (resolves with dose titration) Autoimmune hepatitis and hypersensitivity syndrome	Vaginal discharge Skin changes in areas of sun exposure—dermatitis or hives Changes or discoloration of skin, teeth, or mucous membranes Monitor degree of dizziness as dose is titrated Signs of hypersensitivity syndrome: fever, dermatitis, blistering reactions; systemic symptoms such as malaise, changes in blood pressure, or renal function	Contraindicated in pregnant women or in children younger than 9 years of age Decreased gastrointestinal absorption with Fe, Ca, Mg, Al Sun-avoidance strategies and sunscreen use recommended
Doxycycline	Gastrointestinal upset Photosensitizer (especially at higher doses)	If gastrointestinal side effects occur, monitor hydration Skin changes in areas of sun exposure—dermatitis or hives	Contraindicated in pregnant women or in children younger than 9 years of age Sun-avoidance strategies and sunscreen use recommended
Antisebum			
Combination oral contraceptives	Breakthrough bleeding, headache Serious: venous thromboembolism, hepatotoxicity	Spotting or bleeding	Oral antibiotics may decrease contraceptive efficacy—(significance controversial)
Spironolactone	Common: hyperkalemia, menstrual irregularity, gynecomastia, breast tenderness	Menstrual signs Breast changes	
Anti-inflammatory			
Azelaic acid	Primary: pruritus, burning, stinging, and tingling Other: erythema, dryness, rash, peeling, irritation, dermatitis, and contact dermatitis in less than 1% of patients	Skin changes in areas of sun exposure—dermatitis or hives	Adverse reactions are generally transient and mild in nature
Dapsone	Short- and long-term safety and efficacy demonstrated Peeling, dryness, and erythema	Skin changes in areas of sun exposure—dermatitis or hives	Does not induce phototoxicity or photoallergy in human dermal safety studies Medications such as rifampin,

			anticonvulsants, trimethoprim/sulfamethoxazole, and St John's wort may increase formation of dapsone hydroxylamine (toxicity)

Al, aluminum; Ca, calcium; CYP, cytochrome P450; Fe, iron; Mg, magnesium.

Exfoliants (Peeling Agents)

Exfoliants induce continuous mild drying and peeling by primary irritation, damaging the superficial layers of the skin, and inciting inflammation. This stimulates mitosis, thickening the epidermis, and increasing horny cells, scaling, and erythema. A decrease in sweating results in a dry, less oily surface and may superficially resolve pustular lesions.

In the past, a rabbit model was used to study the efficacy of topical exfoliants in retarding tar-induced comedone formation and accelerating their loss (comedolysis). In this animal model, retinoic acid (tretinoin) was most active, compared with benzoyl peroxide and salicylic acid, which were respectively less active. Data from peer-reviewed literature regarding the efficacy of sulfur, resorcinol, sodium sulfacetamide, aluminum chloride, and zinc are limited. Traditional nonprescription exfoliants, including phenol, resorcinol, beta-naphthol, sulfur, Vleminckx solution, and sodium thiosulfate, are weak or ineffective. These agents are not comedolytic given that they affect the superficial epidermis rather than the hair canal. They have been supplanted by superior effective agents. Linoleic acid–rich phosphatidylcholine combined with 4% nicotinamide is suggested as an emulsion treatment that may be effective in normalization of follicular hyperkeratinization, and also provide anti-inflammatory effects.[80,81]

Resorcinol

Although sulfur and resorcinol have been used for many years in the treatment of acne, evidence from peer-reviewed literature supporting their efficacy is lacking.[67] The phenol derivative resorcinol is less keratolytic than salicylic acid. It is noted to be both bactericidal and fungicidal. Products containing resorcinol 1% to 2% have been used for acne, often in combination with other peeling agents such as sulfur or salicylic acid. The FDA considers resorcinol 2% and resorcinol monoacetate 3%, in combination with sulfur 3% to 8%, to be safe and effective and that the combination may enhance the activity of sulfur. However, the FDA is not convinced that resorcinol and resorcinol acetate are safe and effective when used as single ingredients, and has placed such products in category II (not generally recognized as safe and effective, or misbranded).[81]

Resorcinol is an irritant and sensitizer and should not be applied to large areas of the skin or on broken skin. It produces a reversible, dark brown scale on some dark-skinned individuals.

Protective packaging is important as resorcinol is reactive to light and oxygen. It has good solubility in both water and alcohol and is heat stabile. Thus, it is incorporated into a variety of products, including emulsions.[82]

Salicylic Acid

Salicylic acid, a β-hydroxy acid, is a comedolytic agent that is available over the counter in 0.5% to 2% strengths. Clinical trials demonstrating the efficacy or safety of salicylic acid in acne are limited, although it has been used for many years.[67] It is a natural ingredient in many plants such as willow tree or willow bark, and it penetrates the pilosebaceous unit. The comedolytic action depends on concentration: concentrations in commercial preparations (<2%-3%) are generally low. Concentrations less than 2% may in fact increase keratinization, while those between 3% and 6% are keratolytic, softening the horny layer and producing shedding of scales. Its mechanism remains unresolved, attributed to either reduced cohesion of corneocytes or shedding of epidermal cells, rather than breakdown of keratin.

Salicylic acid has no effect on the mitotic activity of normal epidermis and does not influence disordered cornification.[83] It may provide mild antibacterial value, as it is active against *P. acnes*. It offers slight anti-inflammatory activity at concentrations ranging from 0.5% to 5%. Its efficacy against comedones helps to prevent development of inflamed lesions, thus providing a delayed efficacy.[84]

Salicylic acid is effective. As a peeling agent, its relative strength compared with others in this class varies according to the model used in measurement. It is slightly *less* potent than equal-strength benzoyl peroxide when measured with the rabbit ear animal model, and slightly *more* potent when measured with a biologic microcomedone model.[84] Its anti-inflammatory properties may help dry inflammatory lesions.[82] Its comedolytic properties are considered less potent than topical retinoids. It is often used when patients cannot tolerate a topical retinoid because of skin irritation.[85]

Its keratolytic effect may enhance the absorption of other agents. Salicylic acid is a mild irritant and may cause some degree of local skin peeling and discomfort (burning or reddening). It is not a sensitizer. Although the FDA recognizes salicylic acid as safe and effective, the compound offers no advantages over more modern topical agents such as benzoyl peroxide.[81,83,85]

Salicylic acid products are often used as first-line therapy for mild acne because of their widespread availability without a prescription in a variety of formulations. Both wash-off and leave-on preparations are well tolerated. Lower concentrations are sometimes combined with sulfur to produce an additive keratolytic effect. Concentrations up to 5% to 10% can be used for acne, beginning with a low concentration and increasing as tolerance to the irritation develops. However, the maximum strength allowed in nonprescription acne products is 2%. In high concentrations of 20% to 30% in hydroethanolic vehicles, salicylic acid, either alone or in combination, can be used as a peeling agent for comedonal acne and hyperpigmentation. It extrudes closed and open comedones several days after peel, but it must be applied under strict control to offer this adjunctive benefit when treating acne vulgaris.[86]

Sulfur

Sulfur medications often lessen the severity of acne, presumably because of keratolytic and antibacterial action. Sulfur helps to resolve comedones by an exfoliant action. Its popularity is due to its ability to quickly resolve pustules and papules, mask and conceal lesions (as a thick foundation lotion), and produce irritation leading to skin peeling and mild antibacterial action. Sulfur is used in the precipitated or colloidal form in concentrations of 2% to 10%, because it is practically insoluble in water and must be well dispersed. Its stability depends on effective maintenance of the dispersion.[82] Sulfur compounds (eg, sulfides, thioglycolates, sulfites, thiols, cysteines, and thioacetates) are also available and somewhat weaker. Sulfur can cause slight ophthalmic and dermatologic irritation, and patients should be cautioned to avoid eye contact. Use should be discontinued if excessive irritation results. Although it is often combined with salicylic acid or resorcinol to increase its effect, its use is limited by its offensive odor and the availability of more effective agents.[87]

Topical Retinoids

Topical retinoids are prescription vitamin A derivatives with well-documented, randomized, double-blind, placebo-controlled trials supporting their use for acne treatment.[68] Multiple agents are available in a variety of strengths and formulations: tretinoin, adapalene, tazarotene, and trifarotene. Each retinoid binds to a different set of retinoic acid receptors conferring slight differences in activity, tolerability, and efficacy: tretinoin to alpha, beta, and gamma; tazarotene and adapalene, selectively, to beta and gamma; and trifarotene to gamma. Binding to specific nuclear receptors reduces inflammation, and inhibits sebocyte proliferation and differentiation, which reduces sebum production.

Retinoids are the most powerful available peeling agents since normal epithelial cell differentiation is a vitamin A–dependent process. There is no consensus about the relative efficacy of currently available topical retinoids and oral isotretinoin. They are the core of topical therapy because of their ability to target key stages in the development of the disease: they are comedolytic, resolve the precursor microcomedone lesion, and are anti-inflammatory.

Retinoids act to reduce obstruction within the follicle and therefore are useful in the management of both comedonal and inflammatory acne. As a group, they are highly active peelers as they reverse abnormal keratinocyte desquamation.[88] They improve acne vulgaris by inhibiting microcomedone formation, diminishing the number of mature comedones and subsequently, inflammatory lesions. They also normalize follicular epithelium maturation and desquamation. Topical retinoids, unlike isotretinoin, do not decrease production of sebum, but primarily decrease inflammation, normalize keratinocyte differentiation, and increase keratinocyte proliferation and migration.[88]

Retinoids also facilitate acne lesion clearance through secondary effects of loosening and decreasing corneocytes. This increases skin permeability, facilitates absorption of other agents, such as antimicrobials or benzoyl peroxide, and increases penetration of oral antibiotics into the follicular canal. As a result, the overall duration of antibiotic treatment decreases, and the possibility of resistance lessens. Therefore, combination products with oral or topical antimicrobials are available for increased efficacy, faster onset of effects, decreased total antibiotic use and risk of resistance, and shorter duration of treatment.[88] Retinoids may also improve and prevent postinflammatory hyperpigmentation often seen in people with darker complexions who have acne.

Retinoic acid (vitamin A acid or tretinoin) is a powerful exfoliant that slows the desquamation process, reducing numbers of both microcomedones and comedones.[26] Gels and creams are less irritating than solutions.

Stable and fast acting, adapalene has significant anti-inflammatory and comedolytic properties.[88-92] It causes epidermal and follicular epithelium hyperplasia, increased desquamation, keratinocyte differentiation, and loosening of corneocyte connections. Its anti-inflammatory effect is due to the inhibition of oxidative metabolism of arachidonic acid and inhibition of chemotactic reponses.[92] It is better at reducing inflammatory lesions and total lesion count[91] and causes less local irritation because of its mechanisms and receptor specificity than tretinoin or tazarotene.[90-96] Release from lotions and hydroalcoholic gels is more effective than from creams and aqueous gels and a microsphere gel formulation may be less irritating.[88,93] It is a good first-line therapy for colder climates or in patients with sensitive skin.[76]

Adapalene is generally regarded as effective but less irritating than other topical retinoids.[54,70] It is available in fixed-dose combinations in specialized gel vehicles with benzoyl peroxide to increase the efficacy in comparison with monotherapies. This strategy allows for the synergy of adapalene effects on normalizing desquamation with reduction of inflammation due to benzoyl peroxide action against *P. acnes*. Adapalene gel 0.1% is approved in the United States as a nonprescription product for once-daily application by patients aged 12 years and older.

Tazarotene has superior efficacy to parent retinoids, reducing both noninflammatory and ILs. While its exact mechanism is unknown, it is thought to activate retinoid receptors and thereby affect keratinocyte differentiation, and inhibit proinflammatory transcription factors to decrease cell proliferation and inflammation.[47] It penetrates skin but accumulates in the upper dermis. It is as effective as adapalene in reducing noninflammatory and IL counts when applied half as frequently. Compared with tretinoin, it is as effective for comedonal and more effective for inflammatory lesions when applied once daily. Tazarotene foam 0.1% can be used as an alternative vehicle to the gel with less systemic absorption and is a safe and effective formulation.[87,97,98] Tazarotene is not degraded by sunlight.[26]

Trifarotene is a topical selective agonist of RAR-γ, a receptor expressed in skin and not in internal organs. It was evaluated in two vehicle-controlled, 12-week, randomized double-blind studies of more than 2,000 patients aged 9 years and older, with 20% to 30% decrease in both noninflammatory and inflammatory lesions on the face and trunk. In an open-label extension of continued use, more than 70% of patients achieved an Investigator Global Assessment score of 0 or 1 by 52 weeks. It is approved in the United States as a once-daily application to the trunk and face in patients 9 years and older.[99]

Isotretinoin is a systemic retinoid that is reviewed separately below.

Retinoids tend to produce remissions that are maintained for extended periods of time, provided the accompanying irritation does not impede patient adherence. Side effects, including dryness, peeling, erythema, and irritation, can be mitigated by reduced frequency of application. Given any single agent, higher concentrations may be more efficacious, but with greater side effects. The vehicle of any particular retinoid may also decrease tolerability.[91,92] Most retinoids are unstable and insoluble in water.

Topical retinoids should be used cautiously in pregnancy and tazarotene is contraindicated. Tretinoin and adapalene are in FDA category C, while tazarotene, based on large-surface-area use in psoriasis (see Chapter 118, "Psoriasis"), is in FDA category X.[31] Trifarotene should be avoided in pregnancy. Cases of birth defects in the babies of females using trifarotene have been reported, as has adverse effects in pregnant rabbits given trifarotene orally during the period of organogenesis. The drug is also present in the breast milk of rats being fed the medications, and the manufacturer therefore recommends caution, with application only to small areas that would be unlikely to result in systemic absorption and avoidance of application to the nipples.

Skin type and age may influence tolerability in addition to the choice of vehicle. Oily skin may be more resistant, and darker skin is more prone to postinflammatory hyperpigmentation due to retinoid dermatitis. To decrease irritation, start with the lowest concentration and increase as tolerated.

Application of retinoids should be at night, a half hour after cleansing, starting with every other night for 1 to 2 weeks to adjust to irritation. Short contact time starting with 2 minutes and adding 30 seconds per dose can be advised for patients with sensitive skin or in the winter, discontinuing and resuming after a 3-day rest if undue irritation results. Doses can be increased after 4 to 6 weeks if there is no irritation. Gels and creams are less irritating than solutions.

Some formulations of tretinoin are not photostable and should be applied in the evening. Tretinoin also may be oxidized and inactivated by the coadministration of benzoyl peroxide. It is recommended that the two agents be applied at different times. Tretinoin microsphere formulation, adapalene, and tazarotene do not have similar restrictions. Topical retinoids have been associated with an increased risk of photosensitivity; concurrent daily sunscreen can be used to reduce the risk of sunburn.

Adapalene and tazarotene are photo-irritants (not photosensitizers), and sun avoidance and sunscreen use are imperative.[88]

These agents enhance any other topical acne regimen and allow for maintenance of clearance after discontinuation of oral therapy. Since retinoids are ideal for comedonal acne, when used in combination with other agents, they can address all acne variants. Adapalene is available in combination with benzoyl peroxide, and tretinoin is available combined with clindamycin phosphate 1.2%/tretinoin 0.025% gel, approved for those age 12 years or older.[67]

The therapy of acne in children younger than 12 years of age with products approved by the FDA has expanded. Fixed combination benzoyl peroxide 2.5%/adapalene 1% gel and trifarotene are approved for patients 9 years of age or older, and tretinoin 0.05% micronized tretinoin gel for patients 10 years of age or older. All other retinoids are approved by the FDA for patients 12 years of age or older. Current data show that retinoids in younger patients are effective and are not associated with increased irritation or risk.[67]

Overall, topical retinoids are the cornerstone of acne treatment and provide safe, effective, and economical means of treating all but the most severe cases of acne vulgaris. They should be the first step in moderate acne, alone or in combination with antibiotics and benzoyl peroxide, reverting to retinoids alone for maintenance once adequate results are achieved. Their lack of effect in inducing bacterial resistance enables long-term maintenance of remission.

Antibacterial Agents

Choices for antibacterial therapy include benzoyl peroxide, prescription topical and systemic antibiotics, and combination products. These drugs kill *P. acnes* and inhibit the production of proinflammatory mediators by organisms that are not killed.[26]

Benzoyl Peroxide

Benzoyl peroxide is a bactericidal agent that has proven effective in the treatment of acne. It kills *P. acnes* through the release of free oxygen radicals and is also mildly comedolytic. No resistance to this agent has been reported, and the addition of benzoyl peroxide to regimens of antibiotic therapy enhances results and may reduce resistance development.

Benzoyl peroxide is a derivative of coal tar and was first used for acne vulgaris in the mid-1960s, becoming popular once stable formulations aimed at its heat-lability were developed in the mid-1970s.[95] These preparations are the single most useful group of topical nonprescription drugs. Used alone or in combination, benzoyl peroxide is the standard of care for mild-to-moderate papular-pustular acne. It is an agent of first choice when combined with adapalene for most patients with mild-to-moderate inflammatory acne vulgaris and a second choice alternative for patients with noninflammatory comedonal acne.[24,32,67] A systematic review of 22 trials using benzoyl peroxide for acne vulgaris provided evidence that it reduces acne-lesion count, although high-quality evidence is not robust enough for firm conclusions.[100]

Benzoyl peroxide is well absorbed through the stratum corneum and concentrates in the pilosebaceous unit.[101] It has three principle actions useful in both noninflammatory and inflammatory acne. It produces powerful anaerobic antibacterial activity due to slow release of oxygen, thereby acting against gram-positive and gram-negative bacteria, yeasts, and fungi. This nonspecific antibacterial mechanism does not induce resistance with long-term use.[101] It has a rapid (within 2 hours) bactericidal effect that lasts at least 48 hours. As a result, it may decrease the number of inflamed lesions within 5 days. As an indirect effect, it induces suppression of sebum production; it does not reduce skin surface lipids, but is effective in reducing free fatty acids, which are comedogenic agents and triggers of inflammation.[101] Topical benzoyl peroxide 5% lowers free fatty acids 50% to 60% after daily application for 14 days and decreases aerobic bacteria by 84% and anaerobic bacteria (primarily *P. acnes*) by 98%.

Benzoyl peroxide is also comedolytic. While earlier rabbit model studies showed a benzoyl peroxide effect greater than that of salicylic acid, these animal comedones were not physiologic but induced by tar. More recent studies using native microcomedones show an anticomedogenic effect that is only comparatively slight, compared with tretinoin or salicylic acid.[102-104]

Finally, a supplementary benefit of benzoyl peroxide is an indirect anti-inflammatory action, which is due either to its antibacterial or oxidizing effects. This has been reported in several studies and thus can be used to support treatment of predominantly inflamed lesions.[101] The drug's antiacne effect is augmented by increased blood flow, dermal irritation, local anesthetic properties, and promotion of healing.[105-108] Because the primary effect of benzoyl peroxide is antibacterial, it is most effective for inflammatory acne. Many patients with noninflammatory comedonal acne will respond to its peeling action.

Benzoyl peroxide is available in a variety of preparations without a prescription such as topical washes, foams, creams, or gels, and can be used as leave-on or wash-off agents. There is no clear superiority of different preparations in terms of effectiveness. Newer delivery systems to enhance efficacy and tolerability are also being investigated. Strengths available for acne therapy range from 2.5% to 10%. Total skin contact time and formulation can affect efficacy. Lower concentrations (eg, 2.5%-5%), water-based, and wash-off agents may be better tolerated in patients with more sensitive skin.

Cleansers containing benzoyl peroxide are available as nonprescription liquid washes and solid bars of various strengths. The desquamative and antibacterial effectiveness in a soap or wash is minimized by limited contact time and removal with proper rinsing. Alcohol and acetone gels facilitate bioavailability and may be more effective, while water-based vehicles are less irritating and better tolerated. Paste vehicles are stiffer and more drying than ointments or creams, which facilitate absorption and allow the active ingredients to stay localized.

Concentrations of 2.5%, 5%, and 10% in a water-based gel have been compared with the vehicle alone. The 2.5% formulation is equivalent to the 5% and 10% formulation in reducing the number of inflammatory lesions. The lower strength may not be as effective a peeler compared to higher strengths, which is due to an irritancy reaction. Thus, irritant side effects with the 2.5% gel are less frequent than with the 10% gel but are equivalent to the 5% gel. The lowest concentration of benzoyl peroxide should be used for treating patients with easily irritated skin and may lessen irritation when used in combination topical therapy with comedolytic agents.

Therapy is limited by staining and bleaching of hair, bedsheets, and clothing, concentration-dependent irritation, and uncommonly contact allergy. It produces a mild primary irritant dermatitis that subsides with continued use and is more likely to occur in those with fair complexions, a tendency to irritancy, or propensity to sunburn. This irritation is dependent on the concentration and the vehicle, being higher with alcoholic gels compared with emulsion bases.[102] There are rare reports of contact allergic dermatitis. Cross-reactions with other sensitizers, notably Peruvian balsam and cinnamon, are well established. It may cross-sensitize to other benzoic acid derivatives such as topical anesthetics. Concomitant use of an abrasive cleanser may initiate or enhance sensitization.[109]

Another side effect is body odor from breakdown of the benzoyl peroxide that remains on clothing and bedsheets.

Benzoyl peroxide has been combined with prescription agents to improve efficacy, reduce dosing strengths, decrease irritation, and reduce resistance of antibiotics.[110-113]

Benzoyl peroxide is combined with topical retinoids for an antimicrobial effect or used in conjunction with an antimicrobial. It reduces the likelihood of antibiotic resistance. For long-term maintenance therapy, it is recommended as a highly efficient bactericidal agent to be added to a topical retinoid.[24,32]

The adjunctive use of clindamycin/benzoyl peroxide gel with tazarotene cream promotes greater efficacy and may also enhance tolerability. Increased tolerability might be attributed to emollients in the clindamycin/benzoyl peroxide gel formulation.[114] A patented gel formulation of benzoyl peroxide 5%/clindamycin phosphate 1% (clindamycin) containing dimethicone and glycerin was studied both as a monotherapy and in combination with topical retinoid use. Certain additives, such as silicates and specific humectants, reduced irritation by maintaining barrier integrity.[115]

When using single-agent preparations of benzoyl peroxide, the weakest concentration (2.5%) in a water-based formulation is preferred for anyone with a history of skin irritation.[115] There are many suggested routines to initiate therapy. One is to gently cleanse the skin and apply the preparation for 15 minutes the first evening, avoiding the eyes and mucous membranes. A mild stinging and reddening will appear. Each evening the time should be doubled until the product is left on for 4 hours and subsequently all night. Dryness and peeling will appear after a few days. Once tolerance is achieved, the strength may be increased to 5% or the base changed to the acetone or alcohol gels, or to paste. Alternatively, benzoyl peroxide can be applied for 2 hours for four nights, 4 hours for four nights, and then left on all night. It is important to wash the product off in the morning. Other drying agents should be discontinued. Patients with very sensitive skin or demonstrated sensitivity to benzoyl peroxide should not use the product, and it should be discontinued if irritation becomes severe upon use. Contact with eyes, lips, or mouth should be avoided.

A sunscreen is recommended if benzoyl peroxide is used. To avoid interactions, apply the sunscreen during the day and the benzoyl peroxide at night.

Topical Antibacterials

Topical antibiotics for acne accumulate in the follicle, where they can have antibacterial effects (the primary mechanism for efficacy in acne) and anti-inflammatory actions. These agents are best used in combination with benzoyl peroxide (wash-off or leave-on), which increases efficacy and decreases the development of resistant bacterial strains. Monotherapy with topical antibiotics in the management of acne is not recommended because of the development of antibiotic resistance.[116,117] Macrolides, including topical erythromycin and topical clindamycin, are effective and well-tolerated, well-established acne treatments.

Clindamycin is available as a single agent for topical acne therapy. Topical erythromycin has reduced efficacy in comparison with clindamycin because of resistance of cutaneous staphylococci and *P. acnes*.[68] More than 50% of *P. acnes* strains are resistant to topical macrolides. Resistant strains are usually resistant to all macrolides.[118]

Current recommendations discourage topical antibiotic monotherapy in favor of combination therapy with benzoyl peroxide and topical retinoids. Addition of benzoyl peroxide or topical retinoids to the macrolide antibiotic regimen is more effective than monotherapy and mitigates against survival of resistant *P. acnes* populations.

Clindamycin is the preferred macrolide because of potent action, lack of absorption, and its systemic use is limited because it can cause pseudomembranous colitis when given orally or by injection. It is available as a single ingredient topical preparation and can also be combined with benzoyl peroxide. A topical fixed-dose clindamycin phosphate 12% and benzoyl peroxide 30% combination gel once daily was more effective and twice daily at least as effective as clindamycin alone twice daily, with an early onset of action and an acceptable safety and tolerability profile.[119] Erythromycin is available alone and in combination with retinoic acid or benzoyl peroxide. Stable, fixed-combination agents are available with erythromycin 3%/benzoyl peroxide 5%, clindamycin 1%/benzoyl peroxide 5%, and clindamycin 1%/benzoyl peroxide 3.75%. Combination agents may enhance adherence with treatment regimens. Some topical antibiotic–benzoyl peroxide combinations require refrigeration.[62] Tolerance with these agents is excellent; clindamycin alone is pregnancy category B.[68]

Other topical antibiotics that are being studied include fluoroquinolones, such as nadifloxacin and minocycline, but these are not approved for use in patients with acne by FDA. Minocycline 4% foam is approved by FDA for topical treatment of patients aged 9 years and older with inflammatory lesions of nonnodular moderate-to-severe acne vulgaris. Its use has been evaluated in 3 large randomized, double-blind, vehicle-controlled study in patients with moderate-to-severe acne. Once-daily application for 12 weeks was associated with a decrease in inflammatory lesion count of approximately 13% to 17% compared with 10% to 17% with vehicle alone. It is generally well tolerated, with the most common adverse effects including headache (3%), mild erythema (14.2%), inflammatory/post-inflammatory hyperpigmentation (12.4%), and xerosis (6.8%).[120]

Minocycline is formulated in a yellow base, which can stain fabrics but does not permanently stain skin, and there are no reports to date of drug-induced pigmentation associated with topical application. There are additionally no reports to date of bacterial resistance with topical minocycline. It is broken down by benzoyl peroxide; they should be applied 8 hours apart when used concurrently.

Oral Antibacterials

Overview: a systematic evidence-based review of scientific evidence of the efficacy of oral antibiotics for acne was published in 2017. Due to heterogeneity in trials, there is insufficient evidence to support one type, dose, or duration of oral antibiotic over another in terms of efficacy and summarized key points.[121]

- The use of oral antibiotics is reserved for patients with moderate-to-severe inflammatory acne.
- Tetracyclines are considered first-line therapy, while macrolides and trimethoprim/sulfamethoxazole are acceptable alternative agents.
- It is recommended that oral antibiotics be prescribed with concurrent topical therapy for improved efficacy and to combat antibiotic resistance.
- The choice of antibiotic should be determined based on the side effect profile, resistance, cost, and consensus guidelines.
- Oral antibiotics used in the treatment of acne may have unintended effects on nontarget bacteria, and the clinical implications of this warrant further exploration.

Systemic antibiotics are a standard of care in the management of moderate and severe acne and treatment-resistant forms of inflammatory acne. There is evidence to support the use of tetracycline, doxycycline, minocycline, erythromycin, trimethoprim-sulfamethoxazole, trimethoprim, and azithromycin. Studies do not exist for the use of ampicillin, amoxicillin, or cephalexin. However, any antibiotic that can reduce the *P. acnes* population in vivo and interfere with the organism's ability to generate inflammatory agents should be effective.[62] Although erythromycin is effective, use should be limited to those who cannot use one of the tetracyclines (ie, pregnant women or children under 8 years of age because of the potential for damage to the skeleton or teeth). Ciprofloxacin, trimethoprim-sulfamethoxazole, and trimethoprim alone are also effective in instances where other antibiotics cannot be used or for patients who do not respond to conventional treatment.[81,122]

The tetracycline antibiotic family has multiple modes of action, well-understood antibacterial effects, and anti-inflammatory effects that target an additional aspect of pathogenesis.[116,122,123] Through calcium chelation, they inhibit neutrophil and monocyte chemotaxis. Concentrations below the antibiotic threshold still inhibit inflammation and improve both acne vulgaris and acne rosacea.

Tetracycline is no longer the drug of choice in this family; disadvantages include diet-related effects on absorption and the drug's lower anti-inflammatory and antibacterial activity.

The incidence of significant adverse effects with oral antibiotic use is low. However, adverse effect profiles may be helpful for each systemic antibiotic used in the treatment of acne. Vaginal candidiasis may complicate the use of all oral antibiotics.[62] Doxycycline is very commonly a photosensitizer especially at higher doses.

Minocycline has been associated with pigment deposition in the skin, mucous membranes, and teeth, particularly among patients receiving long-term therapy and/or higher doses of the medication. In some instances this is irreversible. Pigmentation occurs most often in acne scars, anterior shins, and mucous membranes. Minocycline may cause dose-related dizziness, which resolves with dose titration; urticaria; hypersensitivity syndrome, autoimmune hepatitis, a systemic lupus erythematosus-like syndrome; and serum sickness-like reactions.[62,116]

The Cochrane collaboration has conducted a review into the efficacy and safety of minocycline, examining 39 randomized controlled trials. These studies show that minocycline is an effective treatment for moderate-to-severe inflammatory acne but present no evidence to support the first-line use of minocycline in acne treatment. The drug is more lipophilic, may act more quickly, and can be taken once daily. However, people treated with minocycline are at a significantly greater risk of developing an autoimmune syndrome than those given tetracycline or no treatment.[124]

Sarecycline (Seysara) is a new, oral, narrow-spectrum tetracycline-derived antibiotic with anti-inflammatory properties. It is specifically indicated for the treatment of inflammatory lesions of non-nodular moderate-to-severe acne vulgaris in patients 9 years of age or older. The mechanism of action in treating acne vulgaris is not known. Sarecycline should be taken with or without food once daily at a weight-based tiered dosage (60 mg if 33-54 kg, 100 mg if 55-84 kg, and 150 mg if 85-136 kg). To reduce the risk of esophageal irritation and ulceration, sarecycline should be administered with adequate amounts of fluid.

The FDA approval of sarecycline in October 2018 was based on two identically designed, large, multicenter, randomized, double-blind, placebo-controlled, phase III studies that assessed use in a total of 2,002 participants 9 years of age or older with moderate-to-severe facial acne vulgaris. Data demonstrated that once-daily sarecycline 1.5 mg/kg significantly improved acne severity based on Investigator's Global Assessment (IGA) success and significantly reduced inflammatory lesion count versus placebo at week 12. Study 1: IGA success, 21.9% versus 10.5%, and mean absolute reduction in number of inflammatory lesions, 15.3 versus 10.2. Study 2: IGA success, 22.6% versus 15.3%, and mean absolute reduction in inflammatory lesions, 15.5 versus 11.1.[125-127]

Bacterial resistance to antibiotics is an increasing problem in acne therapy, particularly because treatments are used over a long period of time.[116] The development of strains with unidentified mutations suggests new evolving mechanisms of resistance. Combined resistance to clindamycin and erythromycin is much more common than resistance to tetracycline. Use of topical antibiotics can lead to resistance largely confined to the skin of treated sites, whereas oral antibiotics can lead to resistance in commensal flora at all body sites. Resistance is more common in patients with moderate-to-severe acne and in countries with high outpatient antibiotic sales. Resistance is disseminated primarily by person-to-person contact, and thus the spread occurs frequently.

There have been an increasing number of reports of systemic infections caused by resistant *P. acnes* in nonacne patients after surgery. A transmission of factors conferring resistance to bacteria other than *P. acnes* has been described.

The most likely consequence of resistance is decreased clinical efficacy of antibiotic-based treatment regimens compared with that in patients with fully susceptible flora.

Studies on *P. acnes* resistance have highlighted the need for treatment guidelines to restrict the use of antibiotics to limit the emergence of resistant strains. Patients with less severe forms of acne should not be treated with oral antibiotics, and where possible such therapy should be limited to the shortest feasible duration (eg, 6-8 weeks). Local patterns of resistance should be considered. The use of systemic antibiotics should be limited (both indication and duration) and topical antibiotic monotherapy should be avoided.

Guidelines advocate early use of combination therapy with retinoids. Often, when oral antibiotics are combined with topical agents, the antibiotic may be discontinued after 6 months of therapy. Nearly 70% of patients with acne require antibiotics for 12 weeks or less if aggressive retinoid therapy is introduced during that time.[116]

Another potential strategy is to eliminate the use of antibiotics and combine other topical agents. Neither retinoids nor benzoyl peroxide creates selective pressure for resistance and is one combination option. Although this approach has been evaluated for efficacy and safety, there is limited evidence of its effect on microbial resistance. In one open label study of adapalene and benzoyl peroxide, baseline counts of antibiotic resistant strains of *P. acnes* were reduced by week 4.[116]

Stricter cross-infection control measures are recommended when assessing acne. Any topical or systemic antibiotic therapy should be combined when possible with broad-spectrum antibacterial agents such as benzoyl peroxide. In addition, isotretinoin use should be initiated earlier in indicated patients, rather than prolonging antibiotic courses.[24,69]

Other Topical Agents

A tyrosine kinase inhibitor, azelaic acid has been used in patients with sensitive skin or of Fitzpatrick skin types IV or greater because of the lightening effect of the product on dyspigmentation.[67]

Azelaic acid possesses activity against all four pathogenic factors that produce acne. It has anti-inflammatory and antibacterial activities. Azelaic acid also normalizes keratinization, which accounts for its anticomedogenic effect. It is a competitive inhibitor of mitochondrial oxidoreductases and of 5-α-reductase, inhibiting the conversion of testosterone to 5-dehydrotestosterone. It also possesses bacteriostatic activity to both aerobic and anaerobic bacteria including *P. acnes*. Azelaic acid is an antikeratinizing agent, displaying antiproliferative cytostatic effects on keratinocytes and modulating the early and terminal phases of epidermal differentiation.[103] It may produce hypopigmentation. Inhibition of thioredoxin reductase by azelaic acid provides a rationale for its depigmenting property.

Azelaic acid 20% cream is used in the treatment of mild-to-moderate inflammatory acne, has an excellent safety profile with minimal adverse effects, and is well-tolerated in comparison with other acne treatments. The most common adverse effects are pruritus, burning, stinging, and tingling; these are reported in 1% to 5% of patients. These are generally transient and mild in nature. Other adverse reactions, such as erythema, dryness, rash, peeling, irritation, dermatitis, and contact dermatitis, were reported in fewer than 1% of patients.

Azelaic acid has beeneffective in clinical trials studied with topical 2% erythromycin, topical 5% benzoyl peroxide gel, and topical 0.05% tretinoin cream in the treatment of mild-to-moderate inflammatory acne. However, the agent has limited efficacy, compared with other antiacne therapies.[62] It is an alternative to first choice therapy for comedonal and all types inflammatory acne, particularly in combination. It is an alternative to topical retinoids for maintenance therapy as its efficacy and safety profile are advantageous for long-term therapy.[24,32,67]

Azelaic acid should be applied twice a day, in the morning and evening. A majority of patients with inflammatory lesions may experience an improvement in their acne within 4 weeks of beginning treatment. However, treatment may be continued over several months, if necessary.

Azelaic acid is in a pregnancy category B and should only be used in pregnant women if medically necessary. Patients with dark complexions should be monitored for early signs of hypopigmentation.

Dapsone, a synthetic sulfone, is available topically as 5% and 7.5% gels for acne, and may be used in sulfonamide-allergic patients. Dapsone's utility is attributable to its anti-inflammatory and antimicrobial properties that improve both inflammatory and noninflammatory acne, with more prominent effects occurring in inflammatory lesions. In clinical trials, topical dapsone showed modest-to-moderate efficacy, primarily in the reduction of inflammatory lesions. Short- and long-term safety and efficacy have been demonstrated.[128]

In a study of 101 adult women with mild-to-moderate inflammatory facial acne and sensitive skin for 12 weeks, topical 5% dapsone gel was effective and minimally irritating. Response to dapsone appears to be influenced by gender, with female patients experiencing a significantly greater reduction in acne lesion counts and a significantly higher clinical success rate following 12 weeks of treatment.[129]

Topical 5% dapsone gel is recommended to be used twice daily for acne. Conversely, dapsone 7.5% gel is indicated once daily. It received FDA approval for use in patients aged 12 years and older based on a pair of 12-week, double-blind, placebo-controlled, randomized trials that included more than 4,300 participants with acne. In these studies, a Global Acne Assessment Score of 0 or 1 with at least a two-grade improvement was achieved in 30% of patients assigned to dapsone 7.5% gel, compared with 21% of vehicle-treated controls. It was extremely well tolerated, with application site dryness and itching rates similar to placebo.[130]

Topical dapsone is especially beneficial for patients exhibiting sensitivities or intolerance to conventional antiacne agents.[131]

Combination therapy with dapsone and topical retinoids may be indicated if comedonal components are present. Topical dapsone 5%, alone or in combination, with adapalene 0.1% or benzoyl peroxide 4% has been safe and efficacious but may be more irritating than other topical agents.[131,132]

Intralesional Steroids

Intralesional corticosteroid injections are effective for individual inflammatory acne nodules. The effect of intralesional injection with corticosteroids (eg, triamcinolone acetonide) is a well-established and recognized treatment for large inflammatory lesions. Cystic acne improved in patients receiving intralesional steroids.[62] Rapid improvement and decreased pain are noted.

Systemic absorption of steroids may occur with intralesional injections. Adrenal suppression was observed in one study. The injection of intralesional steroids may be associated with local atrophy. Lowering the concentration and/or volume of steroid may minimize these complications.

Hormonal Agents

Two topical antiandrogen treatments are now available: clascoterone and topical spironolactone. Systemic antiandrogen agents include oral contraceptives and systemic spironolactone.

Clascoterone is an androgen receptor inhibitor with a greater ability to inhibit inflammatory cytokine synthesis from sebocytes compared to spironolactone. It has been approved in a 1% cream formulation for topical treatment of acne vulgaris in patients 12 years and older based on two randomized, double-blind, vehicle-controlled trials of 1,421 participants 12 years and older with moderate-to-severe facial acne vulgaris. Overall, 62% of participants were female, and 91% were White, with a mean age of 19.7 years. After 12 weeks of twice-daily application, clascoterone cream 1%, produced a significant reduction in absolute noninflammatory lesions from baseline to −19.4 (both trials) versus −13.0 and −10.8 with vehicle, respectively, as well as a reduction in inflammatory lesions from baseline to −19.3 and −20.0 versus −15.5 and −12.6 with vehicle, respectively. The most common side effects were erythema, pruritus, edema, stinging, and burning.[133]

In contrast to systemic spironolactone, topical clascoterone can be used in both males and females. There are no human data on use in pregnancy, but subcutaneous exposure to doses 8 to 39 times maximal recommended human doses resulted in increased malformations in rats and postimplantation loss and resorptions in rabbits. There are no data on safety in lactation or detection of drug or metabolite in human milk.[134]

Oral Contraceptives

Estrogen-containing oral contraceptives can be useful in the treatment of acne in some women. Those approved by the FDA for the management of acne contain norgestimate with ethinyl estradiol and norethindrone acetate with ethinyl estradiol. There is good evidence and consensus opinion that other estrogen-containing oral contraceptives are also equally effective.[62]

The mechanism of action of combination oral contraceptives (COCs) in the treatment of acne is based on their antiandrogenic properties. These hormones decrease androgen production at the level of the ovary and also increase sex hormone-binding globulin, binding free circulating testosterone and rendering it unavailable to bind and activate the androgen receptor. In addition, COCs reduce 5-α-reductase activity and block the androgen receptor.[68]

The risks of COCs must be weighed against the risks of the condition that they are treating or preventing. If COCs are used exclusively for acne, their risks must be compared to the risks of acne. It is important to remember that FDA approval of all COCs for acne specifies that they are approved for the treatment of acne in women who also desire contraception. COCs carry cardiovascular risks, and breast cancer risks in some women, and low estrogen may affect bone mass. However, decreased risks of colorectal, ovarian, and endometrial cancers have been shown.

Oral contraceptives may improve acne for many women with clinical and laboratory findings of hyperandrogenism and in women without these findings.[68]

The Cochrane collaboration conducted a review in 2012 to determine the effectiveness of COCs for the treatment of facial acne compared with placebo or other active therapies. Thirty-one trials with a total of 12,579 women were reviewed.[134]

Combination oral contraceptive use reduced inflammatory and noninflammatory facial lesion counts, severity grades, and self-assessed acne in nine placebo comparison trials, according to the review.

Most studies assessed women over six treatment cycles, which might not be adequate for a chronic condition like acne. In two trials, patients were more likely to discontinue because of adverse events, suggesting even if COCs improve acne, women might not be willing to accept long-term use for acne because of other side effects.

The review concluded that COCs should be considered for women with acne who also want an oral contraceptive.

A meta-analysis review of 32 randomized controlled trials comparing use of antibiotics to oral contraceptive agents for acne concluded that although antibiotics may be superior at 3 months, oral contraceptive agents are equivalent to antibiotics at 6 months in reducing acne lesions and may be a better first-line alternative to systemic antibiotics for long-term acne management in women.[135]

Spironolactone

Spironolactone is an antiandrogenic compound that decreases testosterone production and competitively inhibits binding of testosterone and dihydrotestosterone to androgen receptors in the skin. Spironolactone may cause hyperkalemia, primarily with higher doses or in patients with cardiac or renal compromise. Routine use occasionally causes menstrual irregularity. A 5% spironolactone gel, studied in patients with increased sebum secretion, resulted in a decrease in the total acne lesions with no significant efficacy under the acne severity index.[136,137]

A single center review of 80 female patients with acne treated with systemic spironolactone (median age 19 years; range 14-20) reported complete response in 22.5% of patients, and complete or partial response greater than 50% in 58.8% of subjects. The median dose was 100 mg, and median time to initial and maximal responses were 3 and 5 months, respectively. Responders were more likely to have jawline distribution of acne (70.3% vs 56.3%) and cyclic flares (75% vs 56.3%), although this was not significant. Only three patients experienced side effects (rash, breast tenderness, diarrhea, and headache) and discontinued treatment. There were no reports of symptoms of hypotension, although blood pressure and potassium were not routinely checked in the cohort.[138]

Although not currently FDA approved for the treatment of acne, the 2016 AAD work group supports the use of spironolactone in the management of acne in select women.[68]

Oral Corticosteroids

Oral corticosteroids have two potential modes of activity in the treatment of acne. One study demonstrated that low-dose corticosteroids suppress adrenal activity in patients who have proven adrenal hyperactivity.[139] Low-dose prednisone in doses ranging from 5 to 15 mg daily, administered alone or with high estrogen containing COCs, has efficacy in the treatment of acne and seborrhea. Expert opinion is that short courses of higher dose oral corticosteroids may be beneficial in patients with highly inflammatory disease. Long-term adverse effects of corticosteroids prohibit use as a primary therapy for acne.[68]

Oral Isotretinoin

Isotretinoin has been revolutionary for acne treatment. The risk of potential adverse effects must be weighed against its ability to prevent lifelong and permanent physical and psychologic scarring.[140]

Oral isotretinoin is an isomer of retinoic acid that has been used for many years and is approved by the FDA for the treatment of severe recalcitrant acne vulgaris. Its use results in decreased sebum production, acne lesions, and acne scarring, along with a decrease in symptoms of anxiety and depression. The 2016 AAD guidelines recommend use of oral isotretinoin in patients with moderate acne that is treatment-resistant or that produces physical scarring or significant psychosocial distress.

Oral isotretinoin is a natural metabolite of vitamin A. Its mechanism is elusive, as it does not bind to retinoid receptors. It reduces sebogenesis and may also inhibit sebaceous gland activity, growth of *P. acnes*, inflammation, and improve follicular epithelial differentiation.[141] Systemic isotretinoin exerts a primary effect on comedogenesis, causing a decrease in size and reduction in formation of new comedones.[26] Isotretinoin is the only drug treatment for acne that produces prolonged remission.

The teratogenic effects of oral retinoid therapy are well documented, and it should be prescribed only by those physicians knowledgeable in its appropriate administration and monitoring. Individuals capable of becoming pregnant who are of child-bearing potential must enroll in the approved pregnancy prevention and management program (ie, iPLEDGE) to be treated with isotretinoin. Two different forms of contraception must be started 1 month before and continue at least 1 month (but normally 4 months) after therapy and pregnancy monitoring undertaken before, during, and after therapy.[140]

The efficacy of conventional isotretinoin treatment (0.5-1.0 mg/kg/day for 16-32 weeks, reaching a cumulative dose of 120-150 mg/kg) for acne has been well established. The approved dosage of isotretinoin is 0.5 to 2.0 mg/kg/day.

Initial flaring can be minimized by initiation of lower doses (ie, 0.5 mg/kg/day or less). Many reports document efficacy of low-dose and intermittent isotretinoin treatment. Lower doses can be used for longer time periods, with a total cumulative dose of 120 to 150 mg/kg or the dose can be lowered to 20 mg on alternate days after an initial 2 months of therapy with higher dosage.[142-144] Reports suggest that low-dose regimens are superior to other regimens (conventional or intermittent) in terms of patient satisfaction, tolerability, and efficacy in patients with moderate acne. In patients with severely inflamed acne, an even greater initial dose reduction may be required or pretreatment with oral corticosteroids considered.

Some patients experience a relapse of acne after the first course of treatment with isotretinoin. A retrospective review compared 82 patients who completed two courses of isotretinoin to 160 patients with only one course. Patients receiving a second course had shorter time from clear date to end of the treatment (32.0 ± 43.3 days compared with 65.4 ± 65 days).[145] Despite the small number of patients and retrospective nature of these data, waiting for 2 months without new lesions has been adopted by some practitioners to minimize risk of relapse after achieving target cumulative dosing.

The 2016 AAD guidelines supports initiation of isotretinoin at 0.5 mg/kg/day when appropriate, subsequently increasing to a full dose of 1 mg/kg/day after the first month as tolerated, with a goal cumulative dose between 120 and 150 mg/kg. One recent study of 116 patients found that a cumulative dose of 220 mg/kg or more may result in lower relapse rates, but confirmation will require study in larger populations.[68]

Isotretinoin is highly lipophilic and best absorbed when taken with food. One novel formulation is less dependent on the presence of fat in the gut for absorption.[146] When prescribed, drying agents must be discontinued and replaced with moisturizers.

Because isotretinoin is a vitamin A derivative, it interacts with many of the biologic systems of the body, and consequently has a significant pattern of adverse effects. The pattern is similar to that seen in hypervitaminosis A. Side effects include those of the mucocutaneous (most common), musculoskeletal, and ophthalmic systems, as well as headaches and central nervous system effects. Most adverse effects, including cheilitis and dry nose, eyes, and mouth, are transient and resolve with drug discontinuation.[140] Laboratory monitoring during therapy should include triglycerides, cholesterol, transaminases, and complete blood counts.

Mood disorders, depression, suicidal ideation, and suicides have been reported sporadically in patients taking this drug. A causal relationship has not been established. These symptoms are quite common in adolescents and young adults, the age range of patients who are likely to receive isotretinoin.

Issues regarding responsible and informed use Published data and expert opinion differ with respect to the use of isotretinoin as first-line or reserve therapy, optimal dosing, and risk of depression.[140]

Although some persist in reserving isotretinoin use only for severe acne, nodular or conglobate acne that has not responded to appropriate antibiotics and topical therapy, delaying use of isotretinoin, the most effective choice, poses an ethical problem.[147] Opinions vary on whether or not to restrict use to patients under 12 years and whether to avoid lasers, peelers, or wax epilation for at least 6 months after discontinuation of therapy.[148]

The causal relationship between the use of isotretinoin and risk of depression continues to be scrutinized with no consensus. The issue is complex as depression and suicidal ideation occur with severe acne in the absence of isotretinoin.

There are instances in which withdrawal of isotretinoin has resulted in improved mood, and reintroduction of isotretinoin has resulted in the return of mood changes. Treatment of severe acne with isotretinoin is often associated with mood improvement.[62] There is epidemiologic evidence that the incidence of these events is lower in patients treated with isotretinoin than in an age-matched general population. There is also evidence that the risk of depressed mood is no greater during isotretinoin therapy than during therapy of an age-matched acne group treated with conservative therapy.[62]

A 2016 review on isotretinoin controversies, facts, and recommendations concluded despite common misperceptions, there is weak evidence for increased incidence of depression, suicidality, or inflammatory bowel disease with isotretinoin use, and data indicate that transient increases in transaminases and lipid levels do not typically necessitate discontinuation of therapy.[149]

In 2017, a systematic review and meta-analysis of the literature, with 31 studies, concluded isotretinoin treatment for acne did not appear to be associated with an increased risk for depression and that the treatment of acne appears to ameliorate depressive symptoms.[150] Current literature regarding the association with depression and suicide was reexamined in 2018. It reconfirmed that while those with a personal or family history of mental disorder might be at risk, further studies are needed and no conclusions can be drawn.[151] The current literature is insufficient to support a meaningful causative association, but important study limitations exist. In the absence of definitive evidence, an idiosyncratic effect cannot be excluded. This disputed association remains an important area for future research. Given the prevalence of depression, anxiety, and suicidal ideation/suicide in the general population, and especially the adolescent population who may be candidates for isotretinoin therapy, the prescribing physician should continue to monitor for these symptoms at each visit for early recognition, advise patients about a possible risk of depression and suicidal behavior, and make therapeutic decisions within the context of each individual patient.[68]

Light Therapy

Light therapies are believed to work by killing *P. acnes* and by damaging and shrinking sebaceous glands, reducing sebum output and have few[152] or temporary[153,154] adverse effects. Light therapies may be used once or twice weekly as a course of 6 to 10 treatments, with each irradiation lasting 10 to 20 minutes.[154] *P. acnes* produce endogenous porphyrins that absorb light to form highly reactive singlet oxygen, which destroys the bacteria.[154] There is still debate about the effectiveness of different wavelengths.[154] Since porphyrins have peak absorption at blue light wavelengths, blue light is often used to treat acne. Red light is also absorbed by porphyrins and can penetrate deeper into the skin,[155] where it may directly affect inflammatory mediators. Other light therapies attempt to selectively target and damage sebaceous glands directly, reducing their size and thus sebum output.[156] These include infrared lasers, low-energy pulsed dye lasers, and radiofrequency devices.[154]

Photodynamic therapy (PDT) uses specific light-activating creams, which are absorbed into the skin and amplify the response to light therapy but tend to produce more severe adverse effects. There are concerns that PDT may interfere with the skin's natural immune mechanisms[157,158] and cause long-term skin damage.

Light therapies, previously expensive and accessed privately via dermatologists or clinics, are increasingly popular. Home-use blue light therapy is now available. Patients find it easier to comply with light treatments because of their short duration.

Very few trials compare light therapy with conventional acne treatments. The European evidence-based guidelines concluded published evidence is scarce and standardized treatment protocols and widespread experience are lacking. Due to conflicting or insufficient evidence, these guidelines did not make a recommendation for or against treatment of comedonal, MMPP, or severe papulopustular/nodular acne with monotherapy visible light, visible or infrared wavelength lasers, or intense pulsed light or PDT. Blue light has a low strength recommendation as a consideration for MMPP.[24,69] An ongoing Cochrane review protocol continues to investigate the current state of evidence for use of light therapy in acne.[159]

Pharmacologic Cleansing Options

Medicated Soaps and Washes

Medicated soaps, washes, and foams may contain topical antiseptics such as triclosan; peeling agents such as salicylic acid, sulfur; antimicrobials such as benzoyl peroxide, clindamycin, or azelaic acid, alone or in combination in low concentrations. They may be nonprescription or prescription status.[160] Most washes should remain on the skin from 15 seconds to 5 minutes followed by thorough rinsing. This limits the amount of time the active ingredient is in contact with the skin. Other cleansers are applied after washing and left on the skin without rinsing.

Quaternary ammonium compounds are cationic detergents that are inactivated quickly in the presence of organic material such as sebum. The duration of action of these products is short.

Antiseptic cleansers that have been studied include hexachlorophene, chlorhexidine, and povidone-iodine. Use of hexachlorophene has since been banned in nonprescription products by the UFDA because of neurotoxicity concerns. Bacteriostatic soaps containing hexachlorophene, carbanilides, and salicylanilides (halogenated hydroxyphenols) may alter normal flora or be acnegenic. Few ordinary soaps induce acne. However, acne patients are particularly susceptible to comedogenic contactants, and if these soaps are applied several times daily for long periods, they may become troublesome.

Soaps containing coal tar, which can induce folliculitis, are not indicated for acne.

In a very small group of patients in an 8-week, double-blind, randomized clinical trial, a combination cleanser containing triclosan, azelaic acid, and salicylic acid produced a greater histopathologic decrease in inflammatory response compared with a nonmedicated cleanser, but there was no significant difference in noninflammatory lesions in either group.[161] A rebound tendency was noted for the nonmedicated cleanser with respect to inflammatory lesions at 4 weeks. Authors concluded that nonmedicated cleansers were an easier and cheaper way of managing patients with mild acne.

Chlorhexidine inhibits in vitro growth of *P. acnes.*[162] A 4% chlorhexidine gluconate preparation in a detergent base is as effective as benzoyl peroxide washes in patients with mild acne, and both preparations reduced the number of inflammatory and noninflammatory lesions after 8 and 12 weeks, compared with vehicle alone.[161] However, further evidence is lacking, and irritation is a side effect.[49]

Glycolic 1%, an alpha-hydroxy acid (AHA), has been used as a cleanser. AHAs cause desquamation by decreasing basal corneocyte cohesion and limiting follicular occlusion. AHA-containing formulations may be considered in the treatment of acne in light of mechanistic similarities with better validated antikeratinization agents such as retinoids.[49]

Alcohol-detergent medicated pads, impregnated with salicylic acid 0.5%, have reduced inflammatory lesions and open comedones in mild-to-moderate acne. This type of medication is less abrasive, not rinsed off, and convenient.[163]

Alcohol-detergent wipes, swabs, or "pledgets" impregnated with antibiotics, such as clindamycin or lincomycin, are available. The antibiotic is deposited in low concentrations on the surface of the skin and may not penetrate to the depths of the pilosebaceous duct. Although patients may like the convenience and perception of using an active agent, they should not be recommended over simple cleansing.

Abrasives consist of finely divided particles of fused aluminum or plastic together with cleansing and wetting agents. Abrasives peel and remove surface debris and may assist resorption of papules and pustules. Despite vigorous rubbing, removal of comedones is not accomplished. Particles containing active agents, such as sodium tetraborate decahydrate, dissolve on use, and their abrasiveness is therefore limited.[163] The effectiveness of an abrasive cleanser with and without polyethylene granules showed no difference in results in patients with mild-to-moderate acne. These products are not indicated in most cases but may be used in a patient who responds empirically.[164]

EVALUATION OF THERAPEUTIC OUTCOMES

⑩ Provide a monitoring framework for patients with acne. Parameters should be monitored by the patient and recorded in a diary. Therapy should be appropriately tapered in response to improvement or resolution. The healthcare professional should be responsible for ensuring that the treatment plan remains on schedule and is effective with no adverse effects. The patient should be contacted within 2 to 3 weeks to determine progress.

Acne is poorly understood by adolescents. These patients often lack knowledge of the cause of the disorder and aggravating factors, indications for self-care versus prescription treatment, expected onset of effect, sequence of the healing process, duration of treatment, appropriate application of topical agents, maximal achievable effects, expected adverse effects, safety concerns, and the benefit to QOL. Clinicians should review patient understanding of each of these important factors to ensure patient adherence. There is often a need to supplement counseling sessions with written materials to which the patient can refer at home.

Good adherence is the key to treatment success. Other strategies to increase adherence include use of once-daily regimens, online follow-up visits, and remote digital imaging for ongoing lesion assessment.[165,166] A randomized controlled trial compared the effectiveness of automated online counseling to standard web-based education on improving acne knowledge. While both models had a significant increase in knowledge from baseline, after 12 weeks, mean improvement in knowledge was higher in the automated counseling group than in the standard Website group. The automated counseling Website group rated their educational material more useful and more enjoyable to view than did the standard Website group. Internet-based patient education appears to be an effective method of improving acne knowledge among adolescents.[167]

Monitoring of the Pharmaceutical Care Plan

Tables 117-2 to 117-4 provide a guide for monitoring patients with acne. Table 117-2 outlines individual drugs, their most common adverse effects, parameters to monitor, and issues to note. Table 117-3 outlines general effectiveness and safety end points, monitoring parameters, and degree of change and time frames for short- and long-term outcomes. Table 117-4 is a guide for monitoring acne patients with consideration to the severity grading of acne types I through IV.

TABLE 117-3

Monitoring Therapy for Acne: Parameters and Frequency

Person Responsible and Frequencies for Monitoring:		
Patient: daily while on drug therapy; Pharmacist: every 4-8 weeks of therapy or next pharmacy visit		
Parameter	**Time Frame / Degree of Change**	**Actions**
Short-Term Effectiveness End Points (Acne Resolution/Control)		
Lesion count	Decrease by 10%-25% within 4-8 weeks, with control, or more than a 50% decrease within 2-4 months	If end points are not achieved, refer to a physician for further therapy
Comedones	Resolve by 3-4 months	
Inflammatory lesions	Resolve within a few weeks	
Anxiety, depression	Achieve control or improvement within 2-4 months	
Long-Term Effectiveness End Points (Acne Resolution/Control)		
Progression of severity	No progression of severity	If end points are not achieved, refer to a physician for further therapy
Recurrent episodes	Lengthening of acne-free periods throughout therapy	
Scarring or pigmentation	No further scarring or pigmentation throughout therapy	
Safety End Points (Treatment Side Effects)		
Dermatitis, increased dryness, gastrointestinal upset, photosensitivity	No adverse effects	Refer to a physician for alternate therapy, dose reduction, discontinuation or additive palliative treatment, or preventative measures for adverse effects

TABLE 117-4

Monitoring Care Plans for Acne Types I Through IV

Acne Type	Description	Suggested Options	Follow-Up Action If Patient Responds	Follow-Up Action If Patient Does Not Respond in 3 Months	Adjustment in Therapy If Patient Does Not Respond Adequately to Previous Action
Type I	Mainly comedones with an occasional small inflamed papule or pustule; no scarring present	Topical retinoid or a fixed combination with a retinoid is the drug of choice; can also consider benzoyl peroxide or azelaic acid or salicylic acid	Continue until lesions are completely cleared and then stop or taper therapy	Treat as Type II acne	
Type II	Comedones and more numerous papules and pustules (mainly facial); mild scarring	Fixed-dose combination (adapalene and benzoyl peroxide) or benzoyl peroxide or topical retinoid or azelaic acid; if more severe, fixed-dose combination is preferred, with or without hormonal therapy and/or antibiotic, particularly if the trunk is involved	Continue until lesions are completely cleared and then stop or taper therapy	Treat as Type III acne	
Type III	Numerous comedones, papules and pustules, spreading to the back, chest, and shoulders, with an occasional cyst or nodule; moderate scarring	Fixed-dose combination with an oral antibiotic is preferred; oral isotretinoin or oral hormonal therapy can also be added	Oral antibiotics typically are prescribed for daily use over 4-6 months, with subsequent tapering and discontinuation as acne improves. Other agents can also be stopped or tapered now	Add oral contraceptive or antiandrogen (women only)	Oral isotretinoin (except in women who are or who may become pregnant); consider safety end points (potential adverse effects) before initiating therapy
Type IV	Numerous large cysts on the face, neck, and upper trunk; severe scarring	For males, monotherapy with oral isotretinoin or a retinoid fixed combination or oral antibiotics; for females, oral isotretinoin plus antiandrogenic hormonal therapy is preferred, or a fixed combination retinoid with oral antibiotics (consider high dose) and/or oral antiandrogenic hormonal therapy	Oral antibiotics typically are prescribed for daily use over 4-6 months, with subsequent tapering and discontinuation as acne improves Other agents can also be stopped or tapered now	If no response after 3-6 months, oral isotretinoin (except in women who are or who may become pregnant). Consider safety end points (potential adverse effects) before initiating therapy	

CONCLUSION

Considerable gaps remain in the understanding of acne, despite all that is known about the pathogenesis of acne and the mechanisms of effective drugs for controlling its symptoms, progression, and complications at structural, biochemical, and physiologic levels. It is still not possible to precisely define the cause of one of the most common skin diseases, nor is it possible to identify a cure for a condition that affects a very large proportion of the global population.

ABBREVIATIONS

BGA	best guideline acne
CAM	complementary and alternative medicine
COC	combination oral contraceptive
CRH	corticotropin-releasing hormone
FDA	Food and Drug Administration
GHQ	general health quality
HGL	high glycemic load
IGF	insulin-like growth factor
MMPP	mild-to-moderate papulopustular
P. acnes	*Propionibacterium acnes*
PAPA	pyogenic arthritis, pyoderma gangrenosum, acne
PBV	pollen bee venom
PDT	photodynamic therapy
QOL	quality of life
SAPHO	synovitis, acne, pustulosis, hyperostosis, osteitis syndrome
SPF	sun protection factor
TTO	time trade-off

SELF-ASSESSMENT QUESTIONS

1. What is the **most accurate** statement regarding the epidemiology of acne vulgaris?

A. Males present with an earlier onset in puberty.

B. Females present with more severe signs and symptoms in puberty.

C. Males have more severe symptoms in adulthood.

D. There are no gender differences in acne prevalence.

2. What is the **most accurate** statement regarding the etiology of acne vulgaris?

A. Acne is generally worse in the summer due to aggravation by ultraviolet light.

B. Aggravation of acne through stress is a myth.

C. Dietary influences may affect the expression of acne.

D. Acne is not more serious if there is a hereditary link.

3. Select the **most important** of four pathophysiologic mechanisms underlying acne vulgaris:

A. Increased follicular keratinization forming a microcomedone

B. Increased production of sebum

C. Bacterial lipolysis of sebum triglycerides to free fatty acids

D. Inflammation

4. What is the **most accurate** statement regarding the clinical presentation of acne vulgaris?

A. The open comedone is the first clinically visible lesion of acne.

B. A pustule is usually greater than 5 mm in diameter.

C. Nodules usually resolve within a few days without scarring.

D. The open comedone is very stable and may persist for a long time.

5. Which of the following factors is the *least* important factor in the *differential diagnosis* of acne vulgaris?

A. Betamethasone therapy

B. Lithium therapy

C. Polycystic ovary syndrome

D. Vitamin B_{12} deficiency

6. Which of the following **can be excluded** as a basic goal of treatment of acne vulgaris?

A. Reversing progression of signs and symptoms

B. Limiting acne duration and recurrence

C. Prevention of long-term disfigurement associated with scarring and hyperpigmentation

D. Avoidance of psychological suffering

7. Which fact is **the least accurate** about comedone extraction?

A. Fewer than 10% of comedone extractions are a complete success.

B. Comedones may recur between 25 and 50 days following expression.

C. Has been widely tested in clinical trials

D. Results in immediate cosmetic improvement

8. To prevent cosmetic acne, patients should:

A. Avoid self-care and use cosmetics applied during a beauty salon facial

B. Select “noncomedogenic” products

C. Select water-based products

D. Avoid hairspray

9. For mild-to-moderate acne with predominantly noninflammatory lesions (comedones), active agents of first choice include:

A. Retinoic acid, topical antibiotics, or benzoyl peroxide

B. Retinoic acid, topical or oral antibiotics, or benzoyl peroxide

C. Topical retinoids (eg, adapalene) or a fixed combination with a retinoid (eg, adapalene plus benzoyl peroxide)

D. Retinoic acid, salicylic acid, or benzoyl peroxide

10. For severe acne with inflammatory lesions (papules, pustules), moderate nodules, and cysts, the most appropriate drug regimens should include:

A. Tretinoin, adapalene, or tazrotene

B. The fixed-dose combination (adapalene plus benzoyl peroxide) with isotretinoin

C. Isotretinoin or topical or oral antibiotics

D. The fixed-dose combination (adapalene plus benzoyl peroxide) with an oral antibiotic

11. Treatment of mild scarring has best results with:

A. Dermabrasion or collagen implants

B. Chemical peels (eg, 70% glycolic acid)

C. Laser therapy

D. Nonprescription alpha-hydroxy acids

12. Comparisons of salicylic acid and benzoyl peroxide have shown:

A. Salicylic acid to be equal or slightly inferior to benzoyl peroxide in reducing number of inflammatory lesions

B. The two products have similar efficacy

C. Benzoyl peroxide could be superior in acting against later steps

D. The effect of different bases is not relevant

13. As a group, the topical retinoids are:

A. Useful in the management of both comedonal and inflammatory acne

B. Ranked in order of peeling efficacy as tretinoin < adapalene < tazarotene

C. Decrease production of sebum and are thus useful for severe acne

D. Are contraindicated in cases of postinflammatory hyperpigmentation

14. Acne patients who wish to increase ultraviolet light exposure to improve acne should use the following therapies with caution:

A. Minocycline and benzoyl peroxide

B. Doxycycline and retinoic acid

C. Retinoic acid and benzoyl peroxide

D. Topical clindamycin and minocycline

15. Choose the **most correct** statement:

A. Azeleic acid therapy should include monitoring for hyperpigmentation.

B. Patients on isotretinoin therapy should be monitored for signs of depression.

C. Control of acne is reflected in a reduction of lesion counts by 50% decrease within 2-4 weeks.

D. Comedones should resolve within a few weeks.

16. Kate presents at a pharmacy with her 3-month-old son Aiden. Aiden has scattered red papules and two to three pustules on both cheeks. There are no blisters or scales. He is not on any medications. He seems fine, he is eating well, and he isn't irritable or fussy. Which of the following is the **most appropriate** recommendation?

A. Hydrocortisone 0.5% cream

B. Benzoyl peroxide 5% lotion

C. An emollient

D. No treatment necessary

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** See section "Epidemiology" of the Acne Vulgaristhis chapter.

2. **C.** See subsection "Dietary Influences" of the Acne Vulgaristhis chapter.

3. **A.** See section "Pathophysiology" of the Acne Vulgaristhis chapter.

4. **D.** See box "Clinical Presentation" in the Acne Vulgaristhis chapter.

5. **D.** See subsection "Differential Diagnosis" of the Acne Vulgaristhis chapter.

6. **A.** Progression of acne cannot be reversed.

7. **C.** As noted in subsection "Comedone Extraction" of the Acne Vulgaristhis chapter, this intervention has not been widely tested.

8. **D.** See subsection "Prevention of Cosmetic Acne" of the Acne Vulgaristhis chapter.

9. **C.** See subsection "Managing Acne" of the Acne Vulgaristhis chapter.

10. **D.** See subsection "Managing Acne" of the Acne Vulgaristhis chapter.

11. **D.** See subsection "Treatment of Scarring" of the Acne Vulgaristhis chapter.

12. **B.** See subsections on Salicylic Acid and Benzoyl Peroxide" of the Acne Vulgaris chapter.

13. **A.** See subsection "Topical Retinoids" of the Acne Vulgaristhis chapter.

14. **B.** Both agents are photosensitizers.

15. **B.** See subsection "Issues Regarding Responsible and Informed Use" of the Acne Vulgaristhis chapter.

16. **D.** Condition is self-limiting and no treatment is needed.

DiPiro's Pharmacotherapy: A Pathophysiologic Approach, 12e >

Chapter 118: Psoriasis

Rebecca M. Law; Wayne P. Gulliver

KEY CONCEPTS

KEY CONCEPTS

① Patients with psoriasis have a lifelong illness that may be visible and emotionally distressing. There is a strong need for empathy and a caring attitude in interactions with these patients.

② Psoriasis is a progressive T-lymphocyte–mediated systemic inflammatory disease that results from a complex interplay between multiple genetic factors and environmental influences. Genetic predisposition and precipitating "trigger" factors play a role in the "march of psoriasis." This march of innate and adaptive immune responses results in clinical expressions (eg, keratinocyte proliferation) and is linked to systemic psoriatic comorbidities.

③ Diagnosis of psoriasis is usually based on recognition of the characteristic psoriatic lesion and not based on laboratory tests.

④ Treatment goals for patients with psoriasis use "treat to target" strategies to reduce disease morbidity and improve quality of life. They serve to minimize signs such as plaques and scales, alleviate symptoms such as pruritus, reduce the frequency of flare-ups, improve the patient's quality of life ensure appropriate treatment of associated comorbid conditions, such as metabolic syndrome, psoriatic arthritis, or clinical depression, and minimize treatment-related morbidity.

⑤ Management of patients with psoriasis generally involves both nonpharmacologic and pharmacologic therapies.

⑥ Nonpharmacologic alternatives such as stress reduction and the liberal use of moisturizers may be beneficial and should always be considered and initiated when appropriate.

⑦ Pharmacologic alternatives for psoriasis include topical agents, phototherapy, and systemic agents (both traditional/nonbiologic and biologic agents).

⑧ Pharmacologic therapy is generally guided by the severity of disease and its impact on the patient's quality of life, advancing from topical agents to phototherapy to systemic agents as needed.

⑨ Rotational therapy (ie, rotating systemic drug interventions) is a means to minimize drug-associated toxicities. However, continuous treatment has replaced rotational or sequential therapy and is now the standard of care for many dermatologists. Rotational and sequential therapy are used in pediatrics. Sequential therapy may be needed for biologics.

⑩ Some biologic agents have proven efficacy for psoriasis; however, there are differences among these agents, including mechanism of action, duration of remission, and adverse-effect profile. Biologics are often used for moderate-to-severe psoriasis and may be first-line therapy especially if comorbidities exist.

BEYOND THE BOOK

BEYOND THE BOOK

What does psoriasis look like? Search online for images of the skin manifestations of the various types of psoriasis (as described in Table 118-1). In particular, for plaque psoriasis (the most common phenotype), search for images of scalp, trunk/limb, hands, and nail involvement (oil spots). This activity is useful to enhance students understanding of the ASSESS step in the patient care process.

INTRODUCTION

Psoriasis is a chronic disease that waxes and wanes. It is never cured, and it is now known to be associated with multiple comorbidities including heart disease, diabetes, and metabolic syndrome. The signs and symptoms of psoriasis may subside totally (go into remission) and then flare up again (exacerbation). Triggers include stress, seasonal changes, and some drugs. Disease severity may vary from mild to disabling. Psoriasis imposes a burden of disease that extends beyond the physical dermatologic manifestations.

① Patients with psoriasis often have a lifelong illness that may be visible and emotionally distressing. There is a strong need for empathy and a caring attitude in interactions with these patients. Thus, management of this condition is necessarily long term and multifaceted, and management modalities may change according to the severity of the illness at the time.

EPIDEMIOLOGY

Psoriasis is the most common immune-mediated inflammatory disease worldwide. In the United States, psoriasis affects about 8 million people, or approximately 3% of the population.[1] The prevalence in countries varies between 0.09% and 11.4%, with differing reasons for the wide range.[2] Climate, sun exposure, and ethnicity are thought to affect prevalence, but correlation between latitude and prevalence is weak.[3]

According to the largest population-based survey—the Multinational Assessment of Psoriasis and Psoriatic Arthritis (MAPP)—the prevalence of psoriasis ranges from 1.4% in Spain to 3.3% in Canada, with the United States at 2.2% and the overall prevalence of psoriasis at 1.9%.[4] Lower frequencies of between 0.4% and 0.7% are seen for people of African and Asian descent.[3] Of interest is the fact that psoriasis is seldom seen in North and South American aboriginal Indians. It affects males and females equally.[5] Psoriasis can present at any age.[4] The majority of patients (approximately 75%) have onset before the age of 40 years,[5] but psoriasis has been observed at birth and as late as the ninth decade of life.[5]

Prevalence increases are roughly linear over the life course (about 0.12% at age 1 year to 1.2% at age 18).[3] Many studies report two peak ages of onset: at 20 to 30 years and again at 50 to 60 years of age.[4,5]

ETIOLOGY

② Psoriasis is a T-lymphocyte–mediated systemic inflammatory disease that results from a complex interplay between multiple genetic factors and environmental influences. Genetic predisposition coupled with some precipitating factor triggers an abnormal immune response, resulting in the initial psoriatic skin lesions. This has been called the “march of psoriasis”[6,7] to reflect the innate and adaptive immune responses that are present. This march leads to expressions of psoriasis with keratinocyte proliferation being central to the clinical presentation of psoriasis and is likely responsible for various comorbidities as a consequence of the chronic inflammation associated with psoriasis.[3,6] For example, there is an association between psoriasis and cardiovascular disease, which is an ongoing, two-way interplay.[6,7] The concept is that systemic inflammation enhances insulin resistance, causing endothelial dysfunction, leading to atherosclerosis and coronary events.[8]

Genetics

Dermatologists have recognized the familial tendencies of psoriasis for many years. Approximately 30% of patients have a first-degree relative with psoriasis, and the risk of psoriasis increases with the number of affected relatives.[4] Monozygotic twins have a concordance rate in the 80% range. Rates of family history in a psoriasis family range between 36% and 91%.[9,10] A study using the founder population of Newfoundland and Labrador noted that more than 80% of the patients had a positive family history.

The bimodal distribution of this disease (prevalence peaking at 20-30 years and again at 50-60 years) may represent two distinct forms of psoriasis, with early-onset psoriasis much more likely to possess a genetic marker highly associated with psoriasis.[4]

There are psoriasis susceptibility genes and variants that reside on various chromosomes. The psoriasis susceptibility locus 1 (*PSORS1*) on chromosome 6p is a key gene locus, accounting for up to 50% of disease heritability.[3] In 2009, studies of the Newfoundland and Labrador population confirmed that major histocompatibility complex antigen HLA-Cw6 and tumor necrosis factor (TNF)-α as major psoriasis susceptibility genes, along with interleukin (IL)-23 loci that had previously been reported.[5,11] The findings have been confirmed in multiple populations worldwide.[12]

Roughly 40 additional loci are thought to be associated with psoriasis.[3] Corresponding genes to these loci are involved in pathogenesis pathways in the immune system (adaptive and innate). There is a general role for T cells and a specific role for TH17 lymphocytes in psoriasis pathogenesis and as indicators of psoriasis risk.[3]

Predisposing Factors and Precipitating Factors

Injury to the skin, infection, drugs, smoking, alcohol consumption, obesity, and psychogenic stress have been implicated in the development of psoriasis. Examples of these precipitating factors include a horsefly bite causing skin trauma and resulting in new-onset psoriasis (known as the *Koebner phenomenon*),[13] a viral or streptococcal infection, or the use of β-adrenergic blockers.[14] Factors exacerbating preexisting psoriasis include drugs[14] (eg, lithium, nonsteroidal anti-inflammatory drugs [NSAIDs], antimalarials such as chloroquine, β-adrenergic blockers, fluoxetine, and withdrawal of corticosteroids), and psoriatic patients commonly have exacerbations during times of stress.[3,14,15] Smoking cigarettes has been shown in two international studies to be a risk factor for psoriasis.[16] Lifestyle intervention to mitigate risk factors has been recommended.[17]

PATHOPHYSIOLOGY

Psoriasis is a common chronic inflammatory disease that involves both adaptive and innate immunity.[3] It is an immune-mediated disease in which the skin inflammatory changes are dependent on immune cells and their cytokines.[4] The interaction between dermal dendritic cells, activated T cells of the TH-1, TH-17 lineage in concert with a multitude of cytokines and growth factors are responsible for the epidermal hyperplasia and dermal inflammation that is seen in the skin of patients with psoriasis. Cross-talk between the innate and adaptive immune system mediated by cytokines including TNF-α, interferon-gamma, and interleukin-1 is a major research focus.[3]

Comorbidities

It is well documented that psoriasis patients have significantly associated comorbidities.[3,4,6,7,16] Approximately 75% of patients will have at least one comorbid condition, and many will have multiple comorbidities.[4] Psoriatic arthritis (PsA) is one of the most common and well-known extracutaneous manifestations of the disease.[4,16] Other associated comorbidities include metabolic syndrome, other immune-mediated disorders such as Crohn’s disease, multiple sclerosis, and some psychological illnesses (anxiety, depression, and alcoholism).[18] Also, malignancies such as cutaneous T-cell lymphoma are associated with psoriasis, and melanoma and nonmelanoma skin cancer are associated with psoriasis treatments.

The National Psoriasis Foundation published a clinical consensus on psoriasis comorbidities with recommendations for screening and addressing issues such as cardiovascular risk, metabolic syndrome, and obesity.[19] The importance of screening for comorbidities in psoriasis patients cannot be overemphasized: nearly half of the psoriatic patients older than 65 years have at least three comorbidities (with two-thirds of this patient population having two or more comorbidities).[20] The presence of specific comorbidity in a patient with psoriasis may influence the choice of pharmacotherapy.

PsA usually develops after the onset of psoriasis,[5] typically 10 years later,[18] with a range of 5 to 12 years.[4] However, 10% to 15% of patients report that the PsA appeared first.[5] The prevalence of PsA in psoriatic patients is about 30%[3,18] but varies by disease severity.[18] In one US study, the prevalences were 14% for patients with mild psoriasis, 18% for those with moderate psoriasis, and 56% for patients with severe psoriasis.[21] PsA most commonly presents as polyarticular peripheral arthritis but can vary widely with peripheral and/or axial, monoarticular, or polyarticular patterns.[4] The severity of PsA also varies widely and does not necessarily correlate with the severity of skin findings.[4] TNF-α and HLA-Cw6 are linked to both PsA and psoriasis.[22] Although immunomodulating treatments for psoriasis (such as methotrexate or TNF-α inhibitors) are useful for PsA, NSAIDs effective for joint symptoms of PsA may exacerbate psoriasis.

Metabolic syndrome is a cluster of risk factors including abdominal obesity, atherogenic dyslipidemia, hypertension, insulin resistance or glucose intolerance, prothrombotic state, and a proinflammatory state.[19] Patients with psoriasis are at increased risk of developing metabolic syndrome.[3,19] The syndrome is a strong predictor of cardiovascular diseases, stroke, and diabetes.[19,23,24] Patients with this syndrome are three times as likely to have a myocardial infarction (MI) or stroke, twice as likely to die from the MI or stroke, and five times as likely to develop type 2 diabetes.[19] A 2010 retrospective analysis of pooled data from three clinical trials (M02-528, CHAMPION, and REVEAL) showed that patients with psoriasis have a 28% and 12% increased 10-year risks of coronary heart disease (CHD) and stroke, respectively.[24]

Psychiatric/psychologic comorbidities include depression, suicidal ideation and suicide, anxiety, and poor self-esteem.[16] A recent meta-analysis reported that more than 25% of psoriasis patients had depressive symptoms and more than 10% were clinically depressed.[16,25] In comparison to control subjects, psoriasis patients had significantly more depression symptoms with an odds ratio (OR) of 1.57% (95% CI 1.40–1.76) for clinical depression (using the International Classification of Diseases codes) and had an OR of 4.24 (95% CI 1.53–11.76) for antidepressant use.[16,25]

Patients with psoriasis also have a decreased life expectancy and increased rates of mortality. Psoriasis is an independent risk factor for atherosclerosis, especially for younger patients with severe disease.[19] A 2006 study found that a relative risk (RR) of death for a 30-year-old person with severe psoriasis was 3.10, after controlling for traditional cardiovascular risk factors (eg, age, gender, hypertension, dyslipidemia, diabetes mellitus, smoking, body mass index [BMI], C-reactive protein [CRP], and family history of cardiovascular disease).[19,26] Three epidemiological meta-analyses identified increased cardiovascular mortality risk (relative risk: 1.39, 1.37, 1.2) and stroke (relative risk 1.56, 1.59, and 1.21) for psoriatic patients.[3] Only patients with severe psoriasis are associated with a higher cardiovascular disease risk.[16] Moderate-to-severe psoriasis may be associated with an increased risk of chronic kidney disease.[16]

Systemic treatment of psoriasis with anti-inflammatory agents—in particular, methotrexate and some biologic therapies—may have protective effects against cardiovascular death, MI, and stroke/cerebrovascular disease.[27,28] However, the use of systemic retinoids does not.[28]

Types of Psoriasis

Plaque psoriasis, also known as *psoriasis vulgaris*, is the most common type of psoriasis (Table 118-1) and is seen in about 90% of psoriasis patients. Plaque psoriasis presents as shown in the Clinical Presentation box.

TABLE 118-1

Phenotypic Classifications of Psoriasis

Plaque (psoriasis vulgaris)
Flexural and/or intertriginous (inverse psoriasis)
Seborrheic
Scalp
Acrodermatitis of Hallopeau
Palm and/or soles
Generalized pustular psoriasis
Guttate
Erythrodermic

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Psoriasis

Signs and Symptoms of Plaque Psoriasis	Description (from Reference 16)
Lesions (plaques)	Erythematous
	Red-violet in color
	At least 0.5 cm in diameter
	Well demarcated—clearly distinguished from normal skin
	Typically covered by silver, flaking scales—scale removal is accompanied by fine points of bleeding (the “Auspitz sign”)
	Lesions may develop at sites of trauma or injury (the “Koebner phenomenon”)
Skin involvement	Either as single lesions at predisposed areas (eg, knees, elbows)
	Or
	Generalized over a wide BSA
	Mild psoriasis: ≤5% BSA involvement
	Moderate psoriasis: PASI ≥8 (higher in trials of biologics)
	Severe psoriasis: The rule of tens: PASI ≥10 or DLQI ≥10 or BSA ≥10% (in some phototherapy trials, BSA ≥20% used as lower limit)
	Categories in the European consensus: Mild psoriasis: BSA ≤10 and PASI ≤10 and DLQI ≤10. Moderate-to-severe psoriasis: (BSA >10 or PASI >10) and DLQI >10
Pruritus	More than 50% of patients with psoriasis have associated pruritus
	May be severe in some patients and may require treatment to minimize excoriations from constant scratching
Other associated concerns	This condition may also be physically debilitating or socially isolating with significant quality-of-life issues for the patient
	Potential comorbidities: PsA, depression, hypertension, obesity, diabetes mellitus, Crohn’s disease, anxiety, alcoholism

BSA, body surface area; DLQI, Dermatology Life Quality Index; PASI, psoriasis area and severity index; PsA, psoriatic arthritis.

Up to 30% of patients with psoriasis have associated PsA[3] but this varies by disease severity.[18] Although nail involvement (psoriatic onychodystrophy) can occur with any type of psoriasis, it is seen in up to 90% of patients with PsA.[16] Fingernails are involved in about 50% of all patients with psoriasis and toenails are involved in 35% of patients.[16]

DIAGNOSTIC CONSIDERATIONS

③ The diagnosis of psoriasis is based on recognition of the characteristic psoriatic lesion and not on laboratory tests. Diagnostic testing is rarely performed as a biopsy may be suggested but is not diagnostic of psoriasis.

Psoriasis is traditionally classified into mild, moderate, or severe disease. In 2011, a European consensus (19 countries) formalized the definition of disease severity and treatment goals and defined plaque psoriasis severity as two main categories: mild versus moderate-to-severe. This became the basis for defining treatment goals in the 2015 European guidelines.[29,30] Both classification systems are in use today. In 2017 the Medical Board of the National Psoriasis Foundation (NPF) used a consensus-building (Delphi) process to establish treatment goals/targets in psoriasis (discussed later).[31] In clinical practice, assessment of the severity of disease includes both an objective evaluation of the extent and symptoms as well as a subjective evaluation of the impact of disease on the patient's quality of life.[16] Assessment typically includes measures of symptom and involvement such as body surface area (BSA), Psoriasis Area and Severity Index (PASI), or Physician's Global Assessment (static PGA), as well as quality-of-life measures such as the Dermatology Life Quality Index (DLQI) or the Short Form (SF-36) Health Survey.[4,16]

Classification of psoriasis as mild, moderate, moderate-severe, or severe disease is generally based on skin lesions and BSA or PASI measurements (see Clinical Presentation box). Practically, to give a rough estimate of BSA involvement, palm size is approximately 1% BSA, head and neck involvement is approximately 10% BSA, both upper limbs approximately 20% BSA, trunk involvement (front and back) approximately 30% BSA, and both lower limbs approximately 40% BSA. The DLQI and other indicators of the disease's impact on a patient's quality of life may also play a role. In 2020, an international group using a Delphi consensus process suggested that in lieu of severity, patients with psoriasis should be classified as either candidates for topical therapy or candidates for systemic therapy[32]; however, this classification differs from the 2021 AAD/NPF treatment guidelines that are discussed later in this chapter.

TREATMENT

Treatment of psoriasis is based on managing the underlying pathophysiology. Agents that modulate the abnormal immune response, such as topical corticosteroids (TCS) and biologic agents, are important treatment strategies for psoriasis. Topical therapies that affect cell turnover, such as retinoids, are also effective for psoriasis. In addition, nonpharmacologic therapies are effective adjuncts and should be considered for all patients with psoriasis. A treatment regimen should always be individualized, taking into consideration severity of disease, patient responses, and tolerability to various interventions. Furthermore, if comorbidities exist, they must be taken into treatment considerations and managed early. Optimal psoriasis care needs to maintain a focus on the patient's overall health-related quality of life.

Desired Outcomes

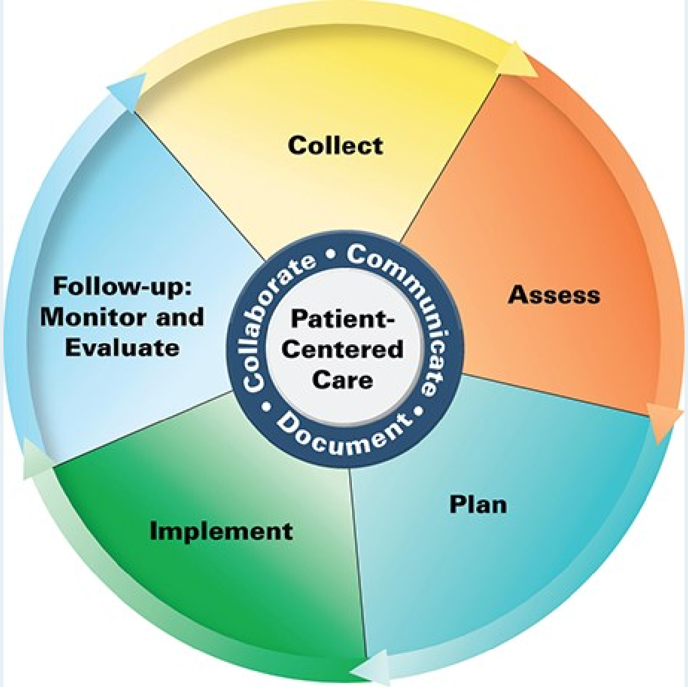
④ Goals of treatment[15]:

- Minimizing or eliminating the visible signs of psoriasis, such as plaques and scales
- Alleviating pruritus and minimizing excoriations
- Reducing the frequency of flare-ups
- Ensuring appropriate treatment of associated comorbid conditions such as PsA, hypertension, dyslipidemia, diabetes, or clinical depression, and ensuring follow-up care for other conditions by appropriate healthcare providers
- Screening for and managing lifestyle factors which may trigger exacerbations (eg, stress, smoking, obesity)[32]
- Minimizing nonspecific triggers such as mild trauma (scratching, piercings, tattoos), sunburn, chemical irritants, environmental/workplace factors[3]

- Optimizing the patient's overall health-related quality of life
- Providing guidance or counseling as needed (eg, stress-reduction techniques, smoking cessation programs)
- Avoiding or minimizing adverse effects from treatments used (topical, phototherapy, and/or systemic)
- Providing cost-effective therapy

PATIENT CARE PROCESS

Patient Care Process for Management of Psoriasis



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex, pregnancy status)
- Patient medical history (personal and family)
- Patient description of history of psoriasis, subjective complaints of itch, and other symptoms
- Signs associated with severity of psoriasis (eg, areas of involvement)
- Signs associated with severity of itch (eg, excoriations, sleep disturbances)
- Signs of other comorbid illnesses (PsA, depression, anxiety, poor self-esteem, Crohn's disease, and metabolic syndrome–associated diseases, eg, dyslipidemia, hypertension, and obesity)
- Signs of secondary skin infections
- Symptoms of stress or distress (personal and family/caregiver)

Assess

- Type of psoriasis (plaque psoriasis being most common)
- Severity of psoriasis—classified into mild, moderate, or severe disease. Mild psoriasis: ≤5% BSA involvement. Moderate psoriasis: PASI ≥8 (higher in trials of biologics). Severe psoriasis: the rule of tens: PASI ≥10 or DLQI ≥10 or BSA ≥10% (in some phototherapy trials, BSA ≥20% used as lower limit). Categories in the European consensus: Mild psoriasis: BSA ≤10 and PASI ≤10 and DLQI ≤10. Moderate-to-severe psoriasis: (BSA >10 or PASI >10) and DLQI >10. Both classifications are in use in North America.
- Severity of itch
- Ability/willingness to pay for medical treatment options
- Emotional concerns for patient and caregiver (if any) and the level of disease-associated stress

Plan

- Determine an appropriate treatment approach, that is, topical or phototherapy or systemic therapy or a combination of treatments
- Determine specific therapeutic agents/treatments of choice
- Recommend the most appropriate therapies (nonpharmacologic and pharmacologic) for this patient's psoriasis
- Manage the itch with appropriate nonpharmacologic and pharmacologic therapies

Implement*

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Provide information about prevention of future flare-ups

Follow-up: Monitor and Evaluate

- Contact patient/caregiver in 1 to 3 weeks (or as recommended based on the specific drug therapy) to follow-up about the efficacy of recommended therapies and any issues with the treatment regimen
- Ensure that appropriate monitoring parameters for efficacy and potential adverse effects have been put in place (eg, follow-up lab tests as needed)
- Reinforce preventive measures including continuation of maintenance therapy
- Ensure that patient/caregiver has been connected to other health resources as needed for follow-up (eg, a psychologist for stress reduction therapy)

Collaborate with patient, caregivers, and other healthcare professionals.

Evaluation of Therapeutic Outcomes

Successful management of psoriasis should include not only clearance of skin lesions, which may take weeks to months depending on the severity of disease, but also control of associated conditions such as itching, and, importantly, comorbidities, including dyslipidemia, hypertension, PsA, and clinical depression as discussed earlier. The ultimate goal is to provide enough control of this chronic disease and its comorbidities (if present) so that the patient's quality of life is optimized.

The 2011 European consensus defined induction and maintenance phases and provided separate treatment goals for induction and maintenance.[29,30] The induction phase is defined as the first 16 weeks of treatment for drugs with a rapid induction to remission (such as adalimumab or infliximab), extending the phase to 24 weeks of treatment for less rapidly effective drugs (such as methotrexate or etanercept).[30] To be considered successful therapy, a treatment regimen should result in a reduction of PASI greater than or equal to 75%, or PASI of 50% to 75% coupled with a DLQI less than 5.[30] Otherwise, treatment modifications should be considered. Treatment goals should be assessed at 10 to 16 weeks and then every 8 weeks thereafter.[30]

In 2017, the NPF-led US consensus recommended earlier treatment response targets: An acceptable treatment response at 3 months after starting new therapies (ie, induction phase) is either BSA 3% or less, or BSA improvement of 75% or more from baseline; the target response at 3 months after starting new therapies is BSA 1% or less.[31] During the maintenance phase, evaluation should occur every 6 months with the target response being BSA 1% or less at every 6 months of maintenance evaluation.[31]

It is important to treat beyond clearing visible skin lesions. Psoriasis is a dermatological inflammatory disorder where the goal is to manage both skin lesions and associated diseases."[32] Comorbidities and trigger factors must be managed as early as possible.

General Approach to Treatment

5 Management of patients with psoriasis generally involves both nonpharmacologic and pharmacologic therapies. Nonpharmacologic management strategies are important and should be used for all patients with psoriasis, regardless of the severity of disease. Pharmacologic therapies are always tailored to the individual patient with psoriasis, and different treatment strategies would be used depending on psoriatic disease severity, presence or absence of comorbid illnesses, and any special considerations such as hepatic or renal dysfunction.

Nonpharmacologic Management Strategies

6 Nonpharmacologic alternatives may be beneficial and should always be considered and initiated when appropriate.[15] These include stress-reduction strategies, moisturizers, oatmeal baths, and skin protection using sunscreens.[33]

In particular, stress reduction has been shown to improve both the extent and severity of psoriasis, and includes methods such as guided imagery and stress-management clinics. Liberal use of nonmedicated moisturizers, applied ad lib, helps to maintain skin moisture, reduces skin shedding, controls associated scaling, and may reduce pruritus. Oatmeal baths further reduce pruritus and with regular use may minimize the need for systemic antipruritic drugs.

Sunscreens, preferably with a sun protection factor (SPF) of 30 or more, should be regularly used because sunburns can trigger an exacerbation of psoriasis. Irritation to the skin should be minimized—harsh soaps or detergents should not be used. Cleansing should be done with tepid water and preferably with lipid-free and fragrance-free cleansers.[15,33]

For patients with comorbidities such as dyslipidemia, obesity, or cardiovascular disease, cessation of nicotine and alcohol consumption, diet management and increasing physical activity can be important interventions.[6,32]

Pharmacologic Therapies

7 Pharmacologic alternatives for psoriasis are topical agents, phototherapy, and systemic agents, including biologic agents (formerly referred to as biologic response modifiers or BRMs).

Drug Treatments of First Choice

8 9 For limited or mild-to-moderate disease, topical treatments are the mainstay of care.[34] Phototherapy and photochemotherapy are used in moderate-to-severe cases.[35] For patients presenting with extensive or moderate-to-severe disease, systemic therapies with or without the use of topical treatments are the usual standard of care.[36,37] Newer systemic treatments such as biologic agents may be the treatments of choice, especially for patients with comorbidities such as PsA or if traditional systemic treatments (such as methotrexate or cyclosporine) are contraindicated.[37] See the "Systemic Therapy with Biologic Agents" section about guidelines for transitioning from traditional nonbiologic systemic agents to biologics.

Once the disease is under control, therapy is reduced in intensity to the least potent, least toxic agent(s) that maintain(s) control. Rotational therapy (ie, rotating systemic drug interventions) may minimize drug-associated toxicities; however, continuous treatment has replaced rotational or sequential therapy and is now the standard of care for many dermatologists. Sequential therapy may be needed for biologics.

Different treatment algorithms are used, depending on the severity of the plaque psoriasis (Figs 118-1 and 118-2). The European consensus categorizes psoriasis as mild or moderate-to-severe with mild disease treated topically and moderate-to-severe disease treated systemically. The Canadian Psoriasis Guidelines Addendum Committee[16] and the British Association of Dermatologists have recommendations for first and alternate choices for biologics (if used)—see the "Systemic Therapy with Biologic Agents" section for details.

Published Guidelines or Treatment Protocols

There are treatment guidelines for both Canada (the Canadian Dermatology Association [CDA])[16] and the United States (American Academy of Dermatology [AAD]).[38-41] In addition, the National Psoriasis Foundation (NPF) has guidelines for use of cyclosporine and methotrexate[42,43] and jointly with AAD for use of topical and alternative medicines in management of psoriasis.[40] In 2011, a 19-country European conference provided a consensus document focusing on disease severity and treatment goals, which ultimately resulted in updated European treatment guidelines in 2015.[29] In 2016, the CDA provided a guideline addendum which updated each chapter of the 2009 guidelines, and in particular, provided more information on use of biologics for treatment of psoriasis.[16] This was followed by new biologics guidelines from the British Association of Dermatologists (BAD) in 2017,[44] and updated joint AAD-NPF biologics guidelines in 2019.[45] AAD-NPF also provided psoriasis guidelines with special attention paid to comorbidities in 2019.[46] As mentioned earlier, the NPF provided guidance about psoriasis treatment targets in 2017 via a consensus study (Delphi method).[31] These guidelines represent the current standards of care.

Topical Therapies

Approximately 80% of patients with psoriasis have mild-to-moderate disease, and the majority of these patients can be treated with topical therapies alone.[40] Individualized approaches are essential because of the wide variation in patients' presentations, their psychosocial health, and their personal opinions as to what would be acceptable treatment.[14,16] Traditional topical therapies include corticosteroids, vitamin D_3 analogs, retinoids, anthralin, and coal tar. In addition, topical calcineurin inhibitors may be useful for difficult-to-treat sites such as the intertriginous areas or the face. Topical biologic agents are being developed and marketed. Topical agents are also used as adjunctive therapy for patients with more extensive disease, who are being treated concurrently with phototherapy or systemic agents.

To determine the quantity of topical agents required, the fingertip unit[47,48] can be used. One fingertip unit is approximately 500 mg,[40,47] which is sufficient to cover one hand (front and back) or about 2% BSA.[48] The trunk (front and back) is about 30% BSA; to cover the entire trunk once, about 15 fingertip units, or 7,500 mg (7.5 g), would be required.

In the United States, the current (2021) treatment guidelines recommend TCS of varying strengths as first-line treatment for limited psoriasis,[40,49] used either as monotherapy or in conjunction with nonsteroidal topical agents; and potency can be enhanced with different vehicles, and as needed by occlusion.[49] Case-based discussions illustrating the guidelines were published in 2010.[49]

In a 2012 systematic review of topical and phototherapies for psoriasis by dermatologists in France, nine recommendations based on evidence and expert opinion are offered. However, quality literature was limited, and the recommendations relating to optimal steroid use and optimal first-line treatment for psoriasis did not reach 80% consensus.[47]

Corticosteroids

TCS have been the mainstay of therapy for the majority of patients with psoriasis for over half a century. They are generally well tolerated, although adverse effects can occur, including systemic ones on occasion. Table 118-2 provides a summary of TCS formulations—including ointments, creams, gels, foams, lotions, sprays, shampoos, tape, and solutions—and potencies.

TABLE 118-2

Topical Corticosteroid Potency Chart

Potency Rating	Corticosteroid—Topical Preparations
Class 1: Superpotent	Betamethasone dipropionate 0.05% ointment (Diprolene and Diprosone ointment)
	Clobetasol propionate 0.05% lotion/spray/shampoo/foam (Clobex lotion/spray/shampoo, OLUX and OLUX-E foam)

	Clobetasol propionate 0.05% cream, gel, solution (scalp), ointment (Cormax, Temovate, Dermovate)
	Diflorasone diacetate 0.05% ointment (Florone, Psorcon, ApexiCon)
	Halobetasol propionate 0.05% cream, lotion, ointment (Ultravate)
	Flurandrenolide tape 4 μg/cm^2 (Cordran)
Class 2: Potent	Amcinonide 0.1% ointment (Cyclocort, Amcort)
	Betamethasone dipropionate 0.05% cream/gel (Diprolene cream, gel, and Diprosone cream)
	Desoximetasone 0.25% cream, gel, ointment (Topicort)
	Diflorasone diacetate 0.05% ointment (ApexiCon, Florone, Psorcon)
	Fluocinonide 0.05% cream, gel, ointment (Lidex)
	Halcinonide 0.1% cream (Halog)
Class 3: Upper mid-strength	Amcinonide 0.1% cream (Cyclocort)
	Betamethasone valerate 0.1% ointment (Betnovate/Valisone)
	Diflorasone diacetate 0.05% cream (Psorcon, Florone, ApexiCon)
	Fluticasone propionate 0.005% ointment (Cutivate)
	Mometasone furoate 0.1% ointment (Elocon)
	Triamcinolone acetonide 0.5% cream and ointment (Aristocort)
Class 4: Mid-strength	Betamethasone valerate 0.12% foam (Luxiq)
	Betamethasone dipropionate 0.05% spray (Sernivo)
	Clocortolone pivalate 0.1% cream (Cloderm)
	Desoximetasone 0.05% cream and gel (Topicort LP)
	Fluocinolone acetonide 0.025% ointment (Synalar)
	Fluocinolone acetonide 0.2% cream (Synalar-HP)
	Hydrocortisone valerate 0.2% ointment (Westcort)
	Mometasone furoate 0.1% cream, lotion, solution (Elocon)
	Triamcinolone acetonide 0.1% ointment (Kenalog)
Class 5: Lower mid-strength	Betamethasone dipropionate 0.05% lotion (Diprosone)

	Betamethasone valerate 0.1% cream and lotion (Betnovate/Valisone)
	Desonide 0.05% lotion, ointment, gel (DesOwen, Tridesilon)
	Fluocinolone acetonide 0.01% shampoo (Capex)
	Fluocinolone acetonide 0.01%, 0.025%, 0.03% cream (Synalar)
	Flurandrenolide 0.05% cream and lotion (Cordran)
	Fluticasone propionate 0.05% cream and lotion (Cutivate)
	Hydrocortisone butyrate 0.1% ointment, lotion, cream (Locoid, Locoid Lipocream)
	Hydrocortisone probutate 0.1% cream (Pandel)
	Hydrocortisone valerate 0.2% cream (Westcort)
	Prednicarbate 0.1% cream and ointment (Dermatop)
	Triamcinolone acetonide 0.1% cream, ointment and lotion (Kenalog)
Class 6: Mild (low potency)	Alclometasone dipropionate 0.05% cream and ointment (Aclovate)
	Betamethasone valerate 0.05% cream and ointment (Valisone)
	Desonide 0.05% cream, ointment, gel (DesOwen, Desonate, Tridesilon)
	Desonide 0.05% foam (Verdeso)
	Fluocinonide acetonide 0.01% cream and solution (Synalar)
	Fluocinonide acetonide 0.01% FS oil (Derma-Smoothe)
Class 7: Least Potent	Hydrocortisone 0.5%, 1%, 2%, 2.5% cream, lotion, spray, and ointment (various brands)

Data from References 54-57.

The most important distinction between corticosteroids is their potency differences. Various potency classification systems are available and Table 118-2 is a compilation with 7 potency classes similar to the 2021 AAD-NPF classification.[40] A comparison of potency classification systems was recently published.[54] Superpotent (class I) TCS provides rapid onset of efficacy but has the greatest risk of adverse effects. Their use should be limited in scope (body area) and duration (2-4 weeks). Clobetasol-17-propionate and betamethasone dipropionate were effective in clearing or markedly improving psoriasis in 75% to 80% of patients in about 3 weeks.[55] Lowest potency TCS should be used on the face and skin folds.

Salt forms of corticosteroids affect potency. For example, betamethasone dipropionate is superpotent to high potency (formulation dependent), whereas betamethasone valerate is medium to lower-mid potency (formulation dependent).

The choice of vehicle affects corticosteroid potency: Ointments, being the most occlusive, enhance drug penetration and provide the most potent formulations. However, patients may prefer a less greasy formulation, such as a cream or lotion for daytime use, although they may be willing to apply the more effective ointment-based corticosteroid during the night.[40] Providing additional occlusion will increase drug penetration of a topical preparation, resulting in enhanced potency. For example, flurandrenolide cream and lotion are potency class 5, but flurandrenolide tape was found to have higher efficacy than diflorasone diacetate ointment (potency class 1).[40,56]

Despite their widespread use, there have been few large-scale, randomized placebo-controlled corticosteroid trials and even fewer head-to-head comparisons with other therapies. The most comprehensive review to date is the analysis of topical psoriasis therapies done in 2002 but recent studies aren't included so this review was already somewhat out of date when published.[16,57] This systematic review found that all TCS treatments considered were efficacious and significantly better than placebo; and that the highest potency corticosteroids were the most efficacious, followed by vitamin D_3 analogs.[16] The French group in 2012 found variable efficacy in their systematic review, noting that recommendations about topical steroid use should be mostly based on expert opinion, and that maintenance intermittent treatment may prolong remission.[58] In addition, TCS used in combination with other agents—topical, systemic, or biologic—may be mutually beneficial. For example, the concomitant use of a second agent may provide a steroid-sparing effect; or the TCS may enhance the efficacy of the second agent. Specifics are discussed in various sections below.

Corticosteroids have anti-inflammatory, antiproliferative, immunosuppressive, and vasoconstrictive effects.[34,40] These are mediated through a variety of mechanisms. Mechanisms of action include binding to intracellular corticosteroid receptors and regulation of gene transcription (in particular, those which code for proinflammatory cytokines).[34,40]

Appropriate use of TCS should include an assessment of disease severity and disease location as well as knowledge of the patient's preference and age. Lower potency TCS should be used for infants and lesions on the face, intertriginous areas, and areas with thin skin. For other areas of the body in adults, mid- to high-potency agents are generally recommended as initial therapy.[40] The highest potency TCS are generally reserved for patients with thick plaques or recalcitrant disease, such as plaques on palms and soles. The use of potency class 1 corticosteroids should be limited to a duration of 2 to 4 weeks,[40] recognizing that the risk of cutaneous and systemic side effects increases with continued use.

Cutaneous adverse effects include skin atrophy, acne, contact dermatitis, hypertrichosis, folliculitis, hypopigmentation, perioral dermatitis, striae, telangiectases, and traumatic purpura.[16,40] Systemic adverse effects have been reported not only with superpotent corticosteroids but also with extended or widespread use of mid-potency agents.[40] Systemic adverse effects include hypothalamic–pituitary–adrenal (HPA) axis suppression and less commonly Cushing's syndrome, osteonecrosis of the femoral head, cataracts, and glaucoma.[40]

Tachyphylaxis can occur with prolonged use, although its clinical significance is difficult to verify.[16] It is recommended that the frequency of use be gradually reduced once clinical response is seen, although there are no established tapering regimens.[40] The French group recommended twice-weekly maintenance therapy.[47] Other approaches include transitioning to weaker potency agents or combination with other nonsteroidal topical therapies.[40] Pulse dosing has also been used to minimize tachyphylaxis and adverse effects.[59]

Vitamin D_3 Analogs

Topical vitamin D_3 analogs include calcipotriol (calcipotriene), calcitriol (the active metabolite of vitamin D), and tacalcitol. Calcipotriol and calcitriol are currently available in the United States and Canada and tacalcitol is available in the United Kingdom. Calcitriol is only available in ointment form; however, calcipotriol is available in ointment, cream, foam, solution, and gel suspension formulations.[34] Other analogs currently under study include maxacalcitol and becocalcidiol. Their mechanisms of action include binding to vitamin D receptors, which results in inhibition of keratinocyte proliferation and enhancement of keratinocyte differentiation.[16] They also have immunosuppressive properties such as inhibiting proinflammatory cytokine production (eg, IL-2 and IFN-gamma) leading to inhibition of T-lymphocyte activity.[16]

Topical calcitriol can be used as first-line monotherapy or in combination regimens for patients with mild plaque psoriasis.[16] The efficacy of calcitriol has been established in large, randomized, double-blind clinical trials.[16] The efficacy of calcipotriol for patients with mild psoriasis is also well established in randomized double-blind placebo-controlled trials. In head-to-head comparison studies with other topical agents, calcipotriol was found to be more effective than anthralin (dithranol)[60] and comparable or slightly more effective than potency class 3 (upper mid-strength) TCS ointments such as betamethasone valerate 0.1% ointment.[16,61,62] In an analysis of topical psoriasis therapies done in 2002,[57] calcipotriol was found to be as effective as all but the most potent TCS.[16,57] Combination therapy with a TCS is particularly effective[63] and is also discussed later in the chapter.

Vitamin D_3 analogs are generally well tolerated and have a good safety profile in comparison with other topical therapies.[63] They have been considered the safest long-term topical treatments.[3] Cutaneous adverse effects most commonly include a mild irritant contact dermatitis; others include burning, pruritus, edema, peeling, dryness, and erythema.[16,40] These adverse effects may be mitigated with continued use.[40] Systemic adverse effects, including hypercalcemia and parathyroid hormone suppression, are rare unless patients are using more than the recommended maximum of 5-mg calcipotriol (100 g of calcipotriol 50 μg/g cream or ointment) per week[16,40] or if there is underlying renal disease or impaired calcium metabolism.[40] When applied sparingly over a BSA <30%, the risk of hypercalcemia is remote.[47]

Calcipotriol is inactivated by ultraviolet A (UVA) light, thus it should be applied after rather than before UVA light exposure.[40] Calcipotriol can be inactivated by acidic substances and thus should not be used with salicylic acid in treating psoriasis.[34] It may also be partially degraded by hydrocortisone valerate.[34] However, calcipotriol is stable with other TCS[63] and stable combinations available in the United States include: calcipotriol and betamethasone dipropionate ointment and suspension (Taclonex) and calcipotriol and betamethasone dipropionate foam (Enstilar).[34] The combination of calcipotriol with betamethasone dipropionate in either ointment or foam results in enhanced efficacy when compared with either agent used alone.[34]

Retinoids

Tazarotene is a topical retinoid that acts through the following mechanisms: normalizing abnormal keratinocyte differentiation, diminishing keratinocyte hyperproliferation, and clearing the inflammatory infiltrate in the psoriatic plaque.[16,40] It is effective in clearing psoriatic plaque lesions and achieving remission.

In a placebo-controlled trial of tazarotene 0.1% and 0.05% gels for patients with plaque psoriasis, tazarotene provided a 50% or greater improvement in 63% (0.1% gel) and 50% (0.05% gel) of patients, respectively, after 12 weeks of use.[64] The therapeutic benefit is maintained for 12 weeks after cessation of therapy.[64] Later clinical trials with tazarotene 0.1% and 0.05% creams versus a placebo vehicle provided similar findings.[65] The 2012 systematic review similarly found that about 50% of patients experienced a 50% or more improvement with no difference in formulations.[47] In comparison to other agents, tazarotene 0.1% gel has similar efficacy to calcipotriol 0.005% ointment (in a small study) but is less effective than clobetasol propionate 0.05% cream.[16] It may be combined with TCS to enhance efficacy and reduce irritation.[34] Fixed combinations are marketed, for example, halobetasol propionate and tazarotene lotion 0.01%/0.045% (Duobrii) received FDA approval in April 2019.

Adverse effects of tazarotene include a high incidence of irritation at the site of application, a dose-dependent effect.[16] This results in burning, itching, and erythema, which can occur in lesional and perilesional skin.[40] Irritation may be reduced by using the cream formulation, lower concentration, alternate-day application, or short-contact (30-60 minutes) treatment.[40] Ad lib use of moisturizers is also beneficial. Tazarotene is also potentially photosensitizing, due to thinning of the epidermis that can occur with continued use.[40]

Tazarotene is contraindicated in pregnancy and should not be used in women of childbearing age unless effective contraception is being used. (All retinoids are potentially teratogenic including topically applied agents. See under section "Retinoids" for further details.)

Anthralin

Anthralin is not as commonly used as other topical therapies currently available for psoriasis; however, there are situations where its use is appropriate and efficacious. It has a direct antiproliferative effect on epidermal keratinocytes,[16,34] normalizing keratinocyte differentiation.[40] Although the exact mechanism of action is unknown, it may have a direct effect on mitochondria[40,66] and reduce the mitotic activity of epidermal cells.[34] It also prevents T-lymphocyte activation.[40] Small placebo-controlled studies demonstrated efficacy for anthralin used continuously or as short contact (1 minute of treatment).[40]

Short-contact anthralin therapy (SCAT) is usually the preferred regimen, where the anthralin ointment is applied only to the thick plaque lesions for 2 hours or less and then wiped off.[15,40] To minimize irritation, it can be applied for 5 to 10 minutes daily initially then titrating up the application time to 20 to 30 minutes or more as tolerated.[34] Because lesions are generally well demarcated, zinc oxide ointment or a nonmedicated stiff paste should be applied to the surrounding normal skin to protect it from irritation and burning. Anthralin should be used with caution, if at all, on the face and intertriginous areas because of the risk of severe skin irritation.[40]

Concentrations for SCAT range from 1% to 4% or as tolerated; concentrations for continuous anthralin therapy vary from 0.05% to 0.4%. Aside from significant and often severe skin irritation, other adverse effects include folliculitis and allergic contact dermatitis, but these are uncommon.

Anthralin powder causes skin irritation. People who handle the dry anthralin powder should avoid skin contact (eg, by wearing gloves while compounding).[15]

Coal Tar

Coal tar was one of the earliest agents used to treat psoriasis. It is keratolytic and may have antiproliferative and anti-inflammatory effects.[15,34] Coal tar formulations include crude coal tar and tar distillates (liquor carbonis detergens—LCD) in ointments, creams, and shampoos. Because of limited efficacy coupled with patient acceptance and compliance issues, coal tar preparations are less commonly used today, especially in North American and European[47] countries.

A 2007 comparative study in Thailand reported that betamethasone valerate was significantly more effective than coal tar.[16,67] Although coal tar may have similar efficacy as calcipotriol,[16] it has a slower onset of action.[16] In addition, coal tar has an unpleasant odor and will stain clothing; thus, it may be cosmetically unappealing to patients. LCD 15% solution was shown to be cosmetically acceptable, well tolerated, and effective when compared with calcipotriol 0.005% cream.[16,68]

Adverse effects include folliculitis, acne, local irritation, and phototoxicity.[16] It is carcinogenic in animals, but for human, no convincing data have emerged regarding carcinogenicity with topical use.[40]

Coal tar concentrations as used in psoriasis treatments (0.5%-5%) are considered safe by the FDA.[69] However, occupational exposure to coal tar, especially in high concentrations such as coal tar used in industrial paving, was reported to increase the risk of lung cancer, scrotal cancer, and skin cancer.[40] The risk of teratogenicity when used in pregnancy is likely to be small, if it exists.[40,69]

Salicylic Acid

Salicylic acid has keratolytic properties and has been used in various formulations including shampoos or bath oils for patients with scalp psoriasis. In combination with TCS, it enhances steroid penetration, thus increasing efficacy.[34] It should not be used in combination with ultraviolet B (UVB) light phototherapy because of a filtering effect that may reduce UVB efficacy.[34] It should not be used with calcipotriol as it inactivates calcipotriol upon contact.[34] Systemic absorption and toxicity can occur, especially when applied to more than 20% BSA[34] or when used for patients with renal impairment.

Avoid the use of salicylic acid in children. However, it may be used for limited and localized plaque psoriasis in pregnancy.[40]

Calcineurin Inhibitors

Topical calcineurin inhibitors such as pimecrolimus 1% cream (Elidel) are marketed for the treatment of inflammatory skin diseases such as atopic dermatitis.[70-72] They are not FDA-approved for psoriasis but are used off-label. Pimecrolimus was found effective for plaque psoriasis when used under occlusion[71] and also effective for patients with moderate-to-severe inverse psoriasis (intertriginous areas are affected).[72] Because this cream is less irritating than calcipotriol and also avoids steroid adverse effects such as skin atrophy, it may be a useful alternative for patients with lesions in intertriginous areas or on the face.[34] Janus Kinase (JAK) Inhibitors Janus Kinase (JAK) Inhibitors Tofacitinib (topical and systemic) and ruxolitinib (topical) are nonbiologic JAK inhibitors. Tofacitinib is currently used off-label for plaque psoriasis (topical and oral) but is indicated for psoriatic arthritis (oral use), rheumatoid arthritis, ankylosing spondylitis, and ulcerative colitis. If used systemically, the dosage must be adjusted for moderate-to-severe renal impairment and moderate hepatic impairment, Tofacitinib is not recommended in severe hepatic impairment. Ruxolitinib is currently indicated for atopic dermatitis.

Combination Topical Therapies Combining agents from different drug classes may be particularly useful in enhancing efficacy or minimizing toxicity.[40] Refer to the "Combination Therapies" section for further information.

Phototherapies and Photochemotherapy

Phototherapy has been used for treating psoriasis for years and is still an important treatment modality today. It has been known for centuries that some skin diseases improve with sun exposure, and clinical studies with phototherapies have been reported since the late 19th century.[38] Phototherapy consists of using nonionizing electromagnetic radiation, either UVA or UVB, as light therapy to treat psoriatic lesions.[73]

UVB is given alone as either broadband or narrowband UVB (NB-UVB), currently with NB-UVB being the preferred method. UVB is also given as photochemotherapy with topical agents such as crude coal tar (Goeckerman regimen)[73] or anthralin (Ingram regimen) for enhanced efficacy.[38]

UVA is generally given with a photosensitizer, such as oral psoralens, to enhance efficacy—this regimen is known as PUVA (photochemotherapy with oral methoxypsoralen and ultraviolet A light).[73]

With respect to comparative efficacy, NB-UVB is more efficacious than broadband UVB, but may be slightly less effective than PUVA.[38,74] PUVA is effective in the majority of patients, with the potential for long remissions.[38] A meta-analysis showed that more patients are still clear at 6 months with PUVA versus with NB-UVB.[74] However, because of greater availability of UVB treatment centers, more evidence available now of the efficacy of UVB treatments for psoriasis (in particular, NB-UVB), and especially the increasing concerns about PUVA toxicities (including skin cancers), phototherapy for psoriasis currently uses UVB or NB-UVB where available. Failure of NB-UVB may justify PUVA therapy.[73]

UVB interferes with protein and nucleic acid synthesis, leading to decreased proliferation of epidermal keratinocytes.[38] UVA has similar effects on epidermal keratinocytes. However, because of deeper penetration into the dermis, it also has effects on dermal dendritic cells, fibroblasts, endothelial cells, mast cells, and skin-infiltrating inflammatory cells including granulocytes and T lymphocytes.[38]

Adverse effects of phototherapy include erythema, pruritus, xerosis, hyperpigmentation, and blistering, especially with higher dosages. It should be used with caution for patients with photosensitivity concerns, and drug interactions include photosensitizing medications such as tetracyclines. Patients must be provided with eye protection during UVB, NB-UVB, or PUVA treatments, and for 24 hours[73] or the remainder of the day[38] after PUVA treatments. In addition, patients receiving PUVA therapy may experience gastrointestinal symptoms such as nausea or vomiting, which may be minimized by taking the oral psoralens with food or milk.[38] For patients also receiving oral retinoids plus PUVA (RE-PUVA), the UVA dose should be reduced by one-third.[38] Long-term PUVA use can lead to photoaging and the development of PUVA lentigines. Psoralens bind to proteins in the lens of the eye; thus, there is a potential for increased cataract formation.

Furthermore, although UVB has a theoretical risk of photocarcinogenesis, the risk is significantly higher with PUVA and is dose related.[38,73] A meta-analysis reported a 14-fold increase in the incidence of squamous cell carcinoma (SCC) in patients receiving high-dose PUVA when compared with low-dose PUVA, with SCC of the male genitalia particularly elevated.[38,75] PUVA may also increase the risk of basal cell carcinoma and possibly melanoma,[38] which may occur 15 years after the first treatment.[73] Thus, the use of phototherapy or photochemotherapy is contraindicated in patients with a history of melanoma or multiple nonmelanoma skin cancers.

Targeted phototherapy using excimer lasers that selectively target psoriatic lesions without affecting normal skin is an option being studied and early results are promising, although blistering and burning of treated lesions are more common, and long-term safety has not been established.[38]

Systemic Therapies

Systemic therapies are the mainstay of treatment for patients with moderate-to-severe psoriasis, with topical therapies remaining as useful adjuncts. However, as discussed below under combination therapies, topical calcipotriol and betamethasone dipropionate ointment may provide sufficient disease control for some patients.[16,76] Conversely, a subset of patients with limited disease may have debilitating symptoms and the use of systemic therapies would be warranted.[39] This may include disease involving "sensitive areas" with significant impact on quality of life (QoL).[54] Systemic therapies include the following traditional agents: acitretin, cyclosporine, methotrexate, mycophenolate mofetil (MMF), and hydroxyurea; as well as the biologic agents, specifically adalimumab, alefacept, etanercept, infliximab, ustekinumab, secukinumab, and newer agents certolizumab, ixekixumab, brodalumab, guselkumab, tildrakizumab, risankizumab, and others at various stages of development.

Acitretin

In the 1980s, etretinate became the first oral retinoid, or vitamin A acid derivative, available for the treatment of psoriasis. It has since been replaced by acitretin, its active metabolite.

Retinoids may be less effective than methotrexate or cyclosporine when used as monotherapy, although the initial response may be more rapid than methotrexate for patients with severe inflammatory forms of psoriasis. Acitretin is more commonly used in combination with topical calcipotriol or phototherapy.[16,39] Its efficacy is dose dependent.[39] Although low-dose acitretin (25 mg/day) is safer and better tolerated than higher-dose (50 mg/day) therapy,[16] low-dose acitretin is not recommended as monotherapy for psoriasis.

Common adverse effects of acitretin include hypertriglyceridemia and mucocutaneous adverse effects such as dryness of the eyes, nasal and oral mucosa, chapped lips, cheilitis, epistaxis, xerosis, brittle nails, and burning or sticky skin.[16,39] Less commonly, "retinoid dermatitis" may occur. Ophthalmologic changes include photosensitivity, decreased color vision, and impaired night vision.[29] GI side effects including hepatitis and jaundice are rare with liver enzyme elevations usually being transient.[29] Periungual pyogenic granulomas are sometimes seen after long-term use of acitretin.[39] Rarely, skeletal abnormalities—such as disseminated idiopathic skeletal hyperostosis (DISH) syndrome—may occur.[16]

All retinoids are teratogenic and are absolutely contraindicated in pregnancy, including topical retinoids. Acitretin should not be used for women of childbearing age unless they are able and willing to use effective birth control not only for the duration of acitretin therapy but also for at least 2 years after discontinuing the agent.[16,29,39] Blood donation (men and women) is not permitted during and for at least a year after treatment.[29] Ethanol should be avoided during therapy and for 2 months after drug discontinuation because it causes the transesterification of acitretin to etretinate, which has a much longer elimination half-life.

Cyclosporine

Cyclosporine is a systemic calcineurin inhibitor. The more bioavailable microemulsion formulation, Neoral, was approved by the FDA in 1997 for the treatment of psoriasis and rheumatoid arthritis.[42]

Cyclosporine is efficacious for both inducing remissions and as maintenance therapy for patients with moderate-to-severe plaque psoriasis. It is also effective in treating pustular, erythrodermic, and nail psoriasis.[42] The 2009 Canadian Guidelines recommended that cyclosporine be normally reserved for intermittent use in periods up to 12 weeks for most patients with psoriasis, for treatment failures, in crisis management, and as a bridge to other therapies such as biologics.[16] Other recommendations are for periods of 1 year or up to 2 years.[42] Risk of toxicity increases with treatment duration: intermittent short-course therapy (<12 weeks) is preferable since this significantly reduces the risk of nephrotoxicity as compared to continuous therapy.[16,29,42]

In comparative randomized controlled trials (RCTs), cyclosporine was significantly more effective than etretinate[77] and similar or slightly better in efficacy than methotrexate.[16,42,78] After inducing remission, maintenance therapy using low doses (1.25-3.0 mg/kg/day) may prevent relapse.[42] The dose should always be titrated to the lowest effective dose for maintenance. In one placebo-controlled study, the relapse rate was 42% for patients on 3.0 mg/kg/day versus 84% for patients on placebo.[79] For patients discontinuing cyclosporine, a gradual taper of 1 mg/kg/day each week may prolong the time before relapse, as compared with abrupt discontinuation.[39,42] Abrupt discontinuation resulted in a dramatic rebound of psoriasis in a few cases.[16] Because more than half of patients discontinuing cyclosporine will relapse within 4 months, patients should be provided with appropriate alternative treatments shortly before or after discontinuing cyclosporine therapy.[42]

Adverse effects of cyclosporine include cumulative renal toxicity, hypertension, and hypertriglyceridemia. The latter two are particularly significant for patients with prior elevation of diastolic blood pressure or triglycerides.[16] Hypertriglyceridemia can occur in up to 15% of patients with psoriasis who are treated with cyclosporine, although this effect is generally reversible upon cessation of therapy.[39] The cyclosporine-induced blood pressure elevation is dose-related, based on a Cochrane systematic review.[80]

The risk of SCC and other nonmelanoma skin cancers increases with duration of treatment[16] and with prior PUVA treatments.[39] Thus, although continuous therapy for up to 2 years may be efficacious,[42] it should be used only in a subset of patients[16] in whom renal function is monitored with annual determinations of glomerular filtration rate (GFR) and monthly measurements of blood pressure and creatinine clearance, with more frequent measurements during the initial 6 weeks of treatment.[16]

Baseline blood pressure, serum creatinine, serum urea nitrogen, triglycerides, complete blood count, uric acid, potassium, and magnesium should be obtained before initiating therapy, every 2 weeks for the first 12 weeks of therapy, and monitored monthly thereafter during therapy.[16,42] If the serum creatinine increases to 25% above the patient's baseline on two occasions (2 weeks apart), the cyclosporine dosage needs to be decreased by 25% to 50%, and serum creatinine rechecked as often as every other week for 1 month. If the serum creatinine does not return to within 10% of the patient's baseline value, a further dose decrease of 25% to 50% should be considered. If the value continues to be greater than 10% above the patient's baseline value, consider discontinuing cyclosporine therapy.[42] (*Note*: A 25% above-baseline cutoff for dosage reduction is the manufacturer's recommendation; the NPF consensus guidelines continue to recommend a 30% cutoff.)[42] Age-appropriate malignancy screening should also be done, and patients should be seen for dental examinations at least yearly because of the risk of gingival hyperplasia.[42]

As a cytochrome P450 isoenzyme 3A4 (CYP3A4) substrate, cyclosporine has significant drug interactions. Serum concentration monitoring is not routinely needed for patients with psoriasis because doses used are lower than in transplant recipients, although monitoring may be advisable for patients taking interacting drugs.

Drugs that can increase cyclosporine concentrations include calcium channel blockers (verapamil, diltiazem, and nicardipine), amiodarone, thiazide diuretics, macrolide antibiotics, allopurinol, oral contraceptives, ezetimibe, selective serotonin reuptake inhibitors (fluoxetine, sertraline), fluoroquinolones (ciprofloxacin, norfloxacin), antifungals (ketoconazole, itraconazole, fluconazole, voriconazole), and cimetidine.[42] Grapefruit juice will also increase cyclosporine concentrations.

Drugs that can reduce cyclosporine concentrations include anticonvulsants (carbamazepine, oxcarbazepine, phenobarbital, phenytoin, valproic acid), rifampin, efavirenz, and St. John's wort.[42]

Conversely, cyclosporine may also affect the drug levels of some drugs. Concurrent use of potentially interacting drugs should be avoided when possible.

The combination of cyclosporine with some topical agents may be beneficial. Refer to the "Combination Therapies" section for details. Cyclosporine should not be used with PUVA due to reduced efficacy and the increased risk of cutaneous malignancies.[42]

Methotrexate

For decades, methotrexate has been the mainstay of systemic therapy for patients with moderate-to-severe psoriasis. It has direct anti-inflammatory benefits due to its effects on T-cell gene expression and also has cytostatic effects.[16] It is more efficacious than acitretin and similar or slightly less efficacious than cyclosporine.[16,43]

Although it also has a significant adverse-effect profile, methotrexate is generally considered a safer alternative than cyclosporine unless there are preexisting contraindications such as liver disease. In some head-to-head clinical studies, more patients dropped out of the cyclosporine treatment arms due to adverse effects.[39,43] While biologic agents are undoubtedly more efficacious, they are much more costly, and some insurance companies require an inadequate response or intolerance to methotrexate (the gold standard) as a prerequisite for approving their use.[43] In a recent placebo-controlled comparative study with adalimumab (CHAMPION), the efficacy of methotrexate was 36% versus 80% for adalimumab and 19% for placebo.[81] Adalimumab also provided a more rapid response; however, the duration of remission is unclear.

Initial doses of 7.5 to 15 mg once weekly may be increased to 20 to 25 mg/week if the response is inadequate at 8 to 12 weeks, with appropriate adverse effect monitoring. Low-dose methotrexate (7.5 to 10 mg/week) in combination with a biologic agent is also recommended.[29] Methotrexate can be used continuously for years or decades with sustained benefits.[16] Methotrexate inhibits folate biosynthesis; and the use of folate supplementation during prolonged methotrexate therapy as seen in dermatology remains controversial. Although some experts recommend folate supplementation for all patients receiving methotrexate for psoriasis, others add folate only when patient issues occur, such as gastrointestinal adverse effects or early bone marrow toxicity (as manifested by an increased mean corpuscular volume) that can be caused by megaloblastic anemia.[39,43] Lack of folate supplementation has also been listed as a risk factor for hepatotoxicity from methotrexate use.[43] One small placebo-controlled study suggested that folate supplementation may result in a slight decrease in efficacy of treatment,[82] but the study methodology has been questioned.[39,43]

The most significant adverse effect is cumulative liver toxicity, and the total lifetime dose of methotrexate must be monitored. Traditionally, patients received a pretreatment liver biopsy and subsequent biopsies when a cumulative dose of 1.5 g is reached. Liver biopsy is the gold standard for assessing histological changes and provides an invasive marker of liver fibrosis. It is recognized that pretreatment liver biopsies may not be practical or appropriate in all cases.[16,43] It has also been recommended that a baseline liver biopsy be delayed for 2 to 6 months so that medication efficacy and tolerability can first be established[43] (ie, intention to continue with methotrexate use). Risk factors for hepatotoxicity from methotrexate include the following: a history of or current alcohol consumption, persistent abnormal liver chemistry studies, history of liver disease including chronic hepatitis B or C, family history of inheritable liver disease, history of significant exposure to hepatotoxic drugs or chemicals, diabetes mellitus, obesity, and hyperlipidemia.[39,43] For patients without preexisting risk factors for hepatotoxicity, it is recognized that they would likely have a low risk of fibrosis and would not require a baseline liver biopsy; furthermore, consideration can be made to continue methotrexate treatment for these patients without biopsies at all, to perform a liver biopsy after 3.5 to 4.0 g total cumulative dose, or to switch therapy to an alternate drug at that point.[39,43]

Currently, liver biopsies are reserved for select high-risk patients. Noninvasive blood serology (FIB-4, Fibrosure, Fibrometer or Hepascore) and LFT monitoring should be performed at baseline prior to starting methotrexate to assess the risk for hepatotoxicity. The additional use of type III serum procollagen as additional monitoring would be ideal, but this is not readily available in the US.[39] The procollagen type III N-terminal peptide (P3NP or PIIINP) serum level is the 2015 European recommendation for MTX monitoring - prior to starting MTX and every 3 months thereafter.[29] As a precaution, a systematic review and meta-analysis of the diagnostic accuracy of noninvasive markers of liver fibrosis in patients with psoriasis taking methotrexate concluded that the clinical utility of LFTs, P3NP, and liver ultrasound is poor, and that if these tests are used in isolation, a significant proportion of patients with liver fibrosis may remain unidentified.[83]

Other adverse effects include significant nausea, pulmonary toxicity, pancytopenia, acute myelosuppression, megaloblastic anemia, and a small but significant increase in lymphoma.[16] Although rare, pancytopenia can occur anytime with the use of low-dose weekly methotrexate and even after single doses of methotrexate.[39] Informing patients about the early symptoms of pancytopenia (dry cough, nausea, fever, dyspnea, cyanosis, stomatitis/oral symptoms, and bleeding) may aid early detection.[29] Methotrexate is an abortifacient and is teratogenic and is absolutely contraindicated in pregnancy. After methotrexate therapy is discontinued, it is recommended that men continue effective birth control for 3 months (since one cycle of spermatogenesis is 74 days), and women should be on effective birth control for at least one ovulatory cycle.[16,39]

Use of folic acid has been shown to reduce hepatic laboratory abnormalities and gastrointestinal side effects in patients with rheumatoid arthritis and also likely reduces hematologic side effects.[39]

Significant drug interactions include serum albumin binding interactions with salicylates, phenytoin, sulfonamides/trimethoprim, ciprofloxacin, and thiazide diuretics, potentially increasing toxicity. Drugs that can reduce methotrexate renal elimination (such as acidic drugs, including salicylates or vitamin C) will also increase serum methotrexate levels and hence increase toxicity. In addition, drugs with hepatotoxic potential may pose an additive risk with methotrexate use.[39]

Janus Kinase (JAK) Inhibitors: Tofacitinib

Tofacitinib is a potent and selective inhibitor of the JAK family of kinases. It inhibits JAK1, JAK2, JAK3, and to a lesser extent TyK2.[84] Inhibition of JAK1 and JAK3 blocks signaling through common receptors for cytokines including IL2, IL4, IL7, IL9, IL15, and IL21.[84] JAK1 inhibition also attenuates signaling by other proinflammatory cytokines (ie, IL6 and Type I interferons).[84]

Tofacitinib is both a topical agent (see above) and an oral agent with a recommended dosage of 5 mg twice daily (or 11 mg of the tofacitinib XR once daily) taken with or without food; the XR tablets must be swallowed whole and cannot be split, crushed, or chewed.[84] There are potential drug interactions with CYP450 substrates—potent CYP3A4 inhibitors (eg, ketoconazole) or modest CYP3A4 plus potent CYP2C19 inhibitions (eg, fluconazole) may increase tofacitinib exposure and potent CYP3A4 inducers (eg, rifampin) may reduce tofacitinib exposure.[84]

Oral Phosphodiesterase Inhibitors: Apremilast

Apremilast is an oral phosphodiesterase inhibitor that downregulates inflammatory responses and may modulate cytokine levels. It is effective for psoriasis, particularly for palmar-plantar or scalp psoriasis, and also for psoriatic arthritis. Apremilast has a good safety profile, with gastrointestinal symptoms being most common (70%–80% occurring within the first 2 weeks of therapy). Depression occurs in about 1% of patients, and it is recommended that patients receive appropriate discussion and counseling before apremilast is initiated to prevent worsening of depression or suicidality.[39] Dose reduction is needed in renal impairment. Weight loss may also occur.

Systemic Therapy with Biologic Agents

⑩ Biologic agents have exploded onto the treatment scenario for many immune conditions, including psoriasis. More and more biologic agents have proven efficacy for psoriasis and have been or approved for use, with many more being used off-label or in various stages of development. Currently available biologic agents include *tumor necrosis factor-α (TNF-α) inhibitors* (etanercept, infliximab, adalimumab, certolizumab), ustekinumab, *IL-17 inhibitors* (secukinumab, ixekixumab, brodalumab), *IL-23 inhibitors* (guselkumab, tildrakizumab, risankizumab), and others. They are recommended for consideration as first-line therapies alongside conventional systemic agents for moderate-to-severe disease. There are differences among these agents, including mechanism of action, duration of remission, and adverse-effect profile. In addition to biologic agents, there are biosimilars to established biologic agents (eg, Amjevita is a biosimilar to adalimumab [Humira]).

General Concerns and Precautions

What precautions are needed when using biologics for treating psoriasis? In general, because of their immunomodulatory effects, there is an increased risk of infection with most of these agents, including serious infections such as sepsis, new-onset or reactivation of tuberculosis, and opportunistic infections such as histoplasmosis, cryptococcosis, aspergillosis, candidiasis, and pneumocystis. The use of live or live-attenuated vaccines during therapy is generally contraindicated. Because biologics are relatively new on the market, the risks of rare but serious adverse effects or those with a longer latency period may still be unrecognized or unreported. Further, clinical trial experience is limited for some biologics, and adequate postmarketing or long-term data are not available. Likewise, safety data on vulnerable populations such as children or women planning a pregnancy are usually absent.[85] There may be more safety data with earlier biologics which had approval for use in rheumatoid arthritis; however, it is the newer classes of biologics which are showing most promise. A 2018 publication concisely addresses the adverse reactions known to-date of biologics used in dermatology—both as indicated and off-label use.[86] In 2020, a Canadian panel of experts (psoriasis, pediatric dermatology, consensus process) considered efficacy and safety of biologics and provided recommendations for use of three biologics in children with moderate-to-severe plaque psoriasis, including a treatment algorithm.[86]

A more recently recognized concern about using biologics is that their efficacy may not be sustainable for much more than three years, that is, there is a loss of effect over time. For example, the British Association of Dermatologists (BAD) Biologic Interventions Register (BAD-BIR) has registered a 53% overall probability of drug survival by year 3, that is, about 50% failure.[85] BAD-BIR currently has more than 10,000 registrations including children.[85] Current data also suggest that failure of one biologic may negatively impact the efficacy of the next, as seen in psoriasis studies.[85] From experience with biologics for rheumatoid diseases, it appears that, after three biologic agents are used, other agents are less likely to be efficacious—there may be a similar phenomenon with their use in psoriasis.

Place in Therapy and Transitioning from Other Therapies

Biologics are often considered for patients with moderate-to-severe psoriasis when other systemic agents are inadequate or relatively contraindicated, or if comorbidities such as active PsA exists. Biologic agents are sometimes recommended for first-line therapy, alongside conventional systemic agents, for patients with moderate-to-severe psoriasis; however, in practice, drug access due to cost considerations may be a limiting factor. The availability of biosimilars may mitigate this to some extent. British Association of Dermatologists (BAD) recommends biologics in methotrexate and cyclosporine failure/intolerance/contraindication; when psoriasis has significant impact on physical, psychological, or social functioning and (a) the psoriasis is extensive (BSA >10 or PASI >=10) or (b) the psoriasis is severe at localized sites and associated with significant functional impairment and/or high levels of distress (eg, nail disease or involvement of high-impact and difficult-to-treat sites such as the face, scalp, palms, soles, flexures, and genitals).[44]

Are there guidelines for transitioning from traditional systemic therapies to biologics? BAD provides some transitioning strategies in their 2017 guidelines[44]: (1) In stable disease, aim to allow 1 month to elapse between the last dose of any current standard systemic immunosuppressive therapy (except MTX) and the planned date of biologic initiation; (2) start a biologic with no drug washout period in patients taking MTX, or on other therapies where a drug washout period would lead to unstable disease; (3) when standard systemic immunosuppressant therapy cannot be stopped (eg, if a disease flare would be severe or hazardous), rationalize the use of therapy and stop as soon as possible (eg, when a minimum response has been achieved).[44]

Biologics may be appropriate/preferred as first-line therapy if comorbidities exist. For example, biologics such as infliximab or adalimumab would be an appropriate treatment option for patients with both plaque psoriasis and active PsA. Biologics currently available for the treatment of psoriasis and/or PsA include adalimumab, brodalumab, certolizumab, etanercept, guselkumab, infliximab, ixekixumab, risankizumab, secukinumab, tildrakizumab, ustekinumab, and others at various stages of development.[37]

Tumor Necrosis Factor-α Inhibitors: Adalimumab, Certolizumab, Etanercept, and Infliximab

The regulation of TNF-α production is associated with various inflammatory conditions, including rheumatoid arthritis, inflammatory bowel disease, ankylosing spondylitis, PsA, and psoriasis.[16,37,41,44,45] Elevated TNF-α levels are seen in both the affected skin and serum of patients with psoriasis; and these elevated levels have a significant correlation with psoriasis severity.[41] The biologic agents adalimumab, certolizumab, etanercept, and infliximab are TNF-α inhibitors; this class of agents is effective for psoriasis and PsA.[16,37,41,44,45,87,88]

There are safety concerns common to TNF-α inhibitors, mainly from observations made through their use in rheumatoid arthritis and inflammatory bowel disease and more recently in psoriasis.[87-89] One concern is an increased risk of bacterial, mycobacterial, invasive fungal (disseminated or extrapulmonary histoplasmosis, aspergillosis, coccidioidomycosis), viral, parasitic, or other opportunistic infections—most commonly upper respiratory tract infections, and less commonly serious infections including sepsis, new-onset or reactivation tuberculosis, and opportunistic infections.[16,41,87-90] There have been reports of serious pulmonary and disseminated histoplasmosis, coccidioidomycosis, and blastomycosis infections, sometimes with fatal outcomes when these infections were not consistently recognized and promptly treated in the patients taking TNF-α inhibitors.[90]

A second concern is the development or worsening of autoimmune diseases such as peripheral and central demyelinating disorders including multiple sclerosis and drug-induced lupus-like syndromes.[16,41,89] Although there is no definitive causal relationship, it is recommended that anti-TNF agents be avoided in patients with established demyelinating diseases (eg, multiple sclerosis), and treatment discontinued in patients with suspected demyelination during therapy.[89] A third concern is the potential increased risk of malignancies such as lymphoma,[16,89,90] melanoma, and nonmelanoma skin cancer.[41] A fourth concern is the potential for other cutaneous adverse effects including vasculitis, granulomatous reactions, cutaneous infections, psoriasiform eruptions, and infusion or injection site reactions.[88] Flares of pustular psoriasis have been reported primarily for patients undergoing treatment for nondermatologic conditions such as rheumatoid arthritis.[16] A fifth concern is the risk of hematologic toxicity including neutropenia (more commonly reported)[89,90] and rare reports of other hematologic events including pancytopenia and aplastic anemia.[90]

There is also a sixth concern about chronic heart failure (CHF): worsening congestive heart failure (CHF) and new-onset CHF have been reported during the use of these agents. TNF-α inhibitors are contraindicated in patients with preexisting moderate-to-severe CHF (NYHA class III/IV),[29,41,90] and those with milder CHF should have their TNF-α inhibitors withdrawn at the onset of new symptoms or worsening of preexisting CHF.[41]

Although the above are safety concerns common to adalimumab, certolizumab, etanercept, and infliximab, their safety profiles are not identical. For example, the risk for tuberculosis (TB) is lowest with etanercept and may be highest with infliximab.[16] Nonetheless, they are contraindicated in patients with active TB.[29] Patients should be evaluated for active or latent TB prior to therapy and considered for a yearly PPD.[16,41] CBC and LFTs are also recommended prior to and periodically during therapy.[29] In addition, pretreatment C-reactive protein (CRP), hepatitis serology (HBV, HCV), and HIV testing have been recommended.[29] They are safe to use in pregnancy.[41] However, some manufacturers have cautioned that, since these agents cross the placenta, infants exposed in utero may be at higher risk of infections and live vaccines would therefore be contraindicated for several months after birth.[90]

Adalimumab is a human monoclonal antibody that provides rapid and efficacious control of psoriasis.[16,41] Adalimumab is indicated for adults with psoriasis, particularly when psoriatic arthropathy is a consideration.[44] Clinical trials in patients with moderate-to-severe psoriasis have shown dramatic results. A 2006 12-week RCT with open-label extension to 52 weeks showed significant improvement within 1 week of therapy, with complete or nearly complete clearance in some patients, and clinical benefits were maintained for at least 1 year with continuous therapy for most patients.[16,91] There is evidence that some patients may achieve/maintain PASI 90 through at least 160 weeks of treatment.[16]

A pivotal 2008 52-week RCT (REVEAL) with an initial 16-week double-blind placebo-controlled (DBPC; period A) phase followed by a 17-week open-label phase (period B) followed by a 19-week DBPC phase (period C) showed a 71% PASI 75 response for adalimumab-treated patients versus 7% for placebo-treated patients at week 16. All patients received open-label adalimumab from weeks 17 through 32. At week 33, patients achieving PASI 75 were rerandomized to adalimumab or placebo; patients achieving PASI 50 but <75 were continued on open-label adalimumab; and therapy for patients with PASI <50 was discontinued. At week 52, 5% of patients rerandomized to adalimumab lost adequate response versus 28% of patients rerandomized to placebo. Adalimumab was continued at 40 mg every other week. The study showed that adalimumab can produce rapid and dramatic results which can be sustained on continued use, in patients with moderate-to-severe psoriasis.[92]

An additional 3-year open-label extension study for patients in REVEAL showed that in patients with sustained initial PASI 75 responses, adalimumab efficacy was maintained for more than 3 years of continuous therapy, and maintenance was best at PASI 100. Some patients with PASI <75 in REVEAL also achieved long-term PASI 75 responses.[87]

For comparative studies, as discussed in the "Methotrexate" section, a head-to-head study showed that adalimumab was significantly more efficacious than methotrexate.[81] For patients who have an inadequate response to other psoriasis treatments (including etanercept), adalimumab is a good alternative.[16]

Adalimumab is given as 80 mg subcutaneously in the first week, then 40 mg the following week, and thereafter 40 mg every other week continuously.[16,29,41,90] More frequent dosing has been explored.[16] For PsA, adalimumab is given as 40 mg subcutaneously every other week, with concomitant use with other medications (analgesics, DMARDs, glucocorticoids, methotrexate, and NSAIDs) allowed, according to product labeling.

Adverse effects in adalimumab clinical trials including the 3-year extension were similar to those already described for this class of biologics.[90]

Etanercept was one of the earliest biologics available on the market for use in inflammatory diseases. It has demonstrated efficacy for rheumatoid arthritis. It was approved for use in PsA in the United States in June 2002 and approved in 2004 for use in moderate-to-severe psoriasis. It is also approved for treatment of juvenile rheumatoid arthritis and ankylosing spondylitis. Thus, as opposed to some of the other biologics approved for psoriasis, etanercept has been extensively used in rheumatology for both adults and children.

The dosing of etanercept in psoriasis differs from its other indications, reflective of the dosing regimens found to be effective for psoriasis in clinical trials. Etanercept is used continuously, given as 50 mg subcutaneously twice weekly for the first 12 weeks, followed by 25 mg twice weekly[16] or 50 mg once weekly.[29,41] Significant improvement was seen in about 50% of patients in clinical trials by week 12 and more than 50% of participants by week 24; with continuing therapy, weaker responders continued to improve for up to 1 year.[16,41,93] Continuing therapy using 50 mg twice weekly regimens is being explored and may provide greater benefit.[16] Etanercept was efficacious in children and adolescents (aged 4-17 years) with plaque psoriasis dosed at 0.8 mg/kg (maximum 50 mg) once weekly.[94] The dosing of etanercept for active PsA is 50 mg by subcutaneous injection once weekly. In patients with moderate-to-severe psoriasis with active PsA, etanercept 50 mg twice weekly for 12 weeks followed by 50 mg once weekly for an additional 12 weeks can be considered, according to product labeling.

Infliximab also received approval for rheumatologic diseases before psoriasis and was on the market before adalimumab. Infliximab is more efficacious than etanercept. A 2011 open-label study showed that psoriatic patients with an inadequate response to etanercept had rapid and sustained improvement when switched to infliximab.[95] Unlike etanercept or adalimumab, infliximab is a chimeric antibody with both murine and human components; thus, antibodies to the drug can develop, resulting in infusion reactions[41,45] and loss of clinical efficacy.[45] The standard dosing regimen is the same for plaque psoriasis and PsA: three IV infusions of 5 mg/kg given over a 6-week induction period, followed by regular infusions every 8 weeks.[41] This 8-week gap between infusions is longer than with other agents, thus increasing the risk of infusion reactions and loss of efficacy due to antibody development in comparison to other biologics.[45]

Clinical response is seen rapidly. In a pivotal phase III RCT, 76% and 70% of patients achieved PASI 75 by week 10 (after 3 doses of infliximab at 5 mg/kg and 3 mg/kg respectively), and PASI 90 was achieved by 45% and 37%, respectively[45,96]; however, the response dropped to about 50% by week 50.[96,97] Combining infliximab with other therapies may enhance response. Methotrexate can reduce the immunogenicity of infliximab, which minimizes the risk of antibody development to infliximab and a consequent loss of clinical response.[45] Enhanced clinical response has been seen in psoriasis and PsA.[45] Thus, the joint AAD-NPF guidelines recommend that the addition of methotrexate to infliximab should be considered strongly for all patients.[45] They caution that the long-term safety of this combination is currently unknown.[45] Infliximab has been combined with TCS and a vitamin D analog to augment efficacy but rigorous evidence supporting this combination is currently lacking.[45]

In addition to antibody development and infusion reactions, serious adverse events, including fatal cases of hepatosplenic T-cell lymphomas, have been reported rarely with infliximab use.[41] Cutaneous adverse effects include nonmelanoma skin cancers; however, these were mostly seen in patients with prior exposure to UV therapy, including NB-UVB and PUVA.[89] Other rare instances of cholecystitis and autoimmune hepatitis, which may be a class effect for TNF-α inhibitors, have also been reported.[16]

Certolizumab pegol is a humanized antigen-binding fragment of a monoclonal antibody that is further conjugated with a polyethylene glycol moiety. This binds to TNF-α, blocking its interaction with TNF receptors.[45] A phase II RCT showed PASI 75 achieved in 75% and 83% of patients by week 10, on doses of 200 mg or 400 mg every other week, respectively, versus 7% for the placebo group.[45,98] Recommended certolizumab dosing is 400 mg (as 2 × 200-mg subcutaneous injections) every 2 weeks, with a dose-reduced regimen for patients under 90 kg (198 lb): 400 mg (as 2 × 200-mg subcutaneous injections) initially and at weeks 2 and 4, followed by 200 mg every other week.[45,99] Recommended initial certolizumab dosing in active PsA is 400 mg (as 2 × 200-mg subcutaneous injections) once and then repeat at weeks 2 and 4. Maintenance dosing for active PsA is 200 mg subcutaneously every other week or 400 mg every 4 weeks, according to product labeling.

IL-12/IL-23 Inhibitors: Ustekinumab

Ustekinumab is an IL-12/23 monoclonal antibody approved for the treatment of moderate-to-severe plaque psoriasis and/or active PsA alone or in combination with methotrexatein adults 18 years or older.[16,26] It has a higher drug survival rate than TNF-α inhibitors, that is, longer duration of efficacy with continued treatment.[45] There is evidence that some patients may maintain PASI 90 through at least 244 weeks of treatment.[16] One study found that patients who had not used a biologic before (ie, biologic-naïve) or were using methotrexate concomitantly had longer survival.[45,100] Ustekinumab was significantly more efficacious than etanercept but less efficacious than the IL-17 inhibitors secukinumab or ixekizumab in clinical trials.[41] Ustekinumab has demonstrated long-term efficacy and safety for up to 5 years.[16] In addition, it is effective for difficult-to-treat areas, including hand and foot (either palmoplantar plaque or pustular), nail, and scalp psoriasis.[41]

Ustekinumab selectively targets IL-12 and IL-23, two cytokines that play a role in the pathogenesis of psoriasis.[29,45] It binds to their shared p40 protein subunit, thus preventing interaction with their cell surface IL-12Rβ1 receptor.[101] This shared binding may allow ustekinumab to exert its clinical effects in both psoriasis and PsA through interruption of the TH1 and TH17 cytokine pathways, central to both disease conditions.[101]

Ustekinumab can provide a rapid response that is seen within 2 weeks of initiating treatment.[45,102,103] Two large randomized placebo-controlled trials (PHOENIX 1[97] and PHOENIX 2[98]) demonstrated clinical efficacy of ustekinumab, with approximately 70% of patients achieving 75% skin clearance after two doses and maintaining the response for 1 year with continued treatment. The improvements were dramatic. Ustekinumab is effective in treating difficult-to-treat areas, such as hand and foot (palmoplantar plaque or pustular), nail, and scalp psoriasis.[45] In active PsA, ustekinumab demonstrated a greater proportion of ACR20 response at week 24 when compared to placebo in adult patients, according to product labeling. There was also a greater proportion of patients on ustekinumab with no or less radiographic progression at week 24 when compared with placebo.

The impact of ustekinumab on patients' health-related QoL was evaluated in the PHOENIX 2 trial.[104] Patients showed a significant improvement not only in skin-related QoL, but also in symptoms of anxiety and depression (as assessed by the Hospital Anxiety and Depression Scale).[103] The subset of patients with PsA in PHOENIX 1 and PHOENIX 2 also showed significant improvement in QoL, anxiety, and depression.[105]

Weight-based dosing rather than fixed-dose was found to be clinically significant for efficacy in PHOENIX 1 and PHOENIX 2—heavier patients required a higher dose.[106] Serum ustekinumab concentrations were also affected by weight.[106] Clinical response is related to serum ustekinumab levels achieved.[101] Manufacturer-recommended dosing is 45 mg for patients weighing 100 kg (220 lb) or less, and 90 mg for those of higher weights. Ustekinumab is administered subcutaneously at weeks 0 and 4, then every 12 weeks thereafter as maintenance therapy.[16,101] This dosing regimen is the same for active PsA alone or in combination with methotrexate. In cases where a loss of response is detected in the patient, the dose can be increased from 45 mg every 12 weeks to 90 mg every 8 weeks to improve response.[16]

Cumulative 3-year safety data from PHOENIX 1 and 2 have been published[107,108] and there is 5-year safety data.[89] Common adverse effects include upper respiratory infections, headache, fatigue, pruritus, back pain, injection site reactions, and arthralgia, with the most common events being headache and nasopharyngitis.[107] Ustekinumab does not exacerbate atopic diseases.[107] Serious adverse effects include those seen with other biologics, including serious tubercular, fungal, viral infections, and cancers. No evidence of a dose-response to infection rates was seen.[108] Serious infections and malignancy rates did not increase with long-term ustekinumab treatment for up to 3 years.[107,108] In addition, a reversible posterior leukoencephalopathy syndrome (RPLS) has been reported.[88,89] Regarding major adverse cardiovascular events (MACE), 5-year follow-up of clinical trials did not show an increased risk with ustekinumab.[89,109] Recommended monitoring parameters (pretreatment and every 3–6 months thereafter) include complete blood count, liver enzymes, serum creatinine, and renal status. In addition, pretreatment CRP and testing for hepatitis B and C and human immunodeficiency virus have been recommended.[29] Contraindications include clinically important active infection (including untreated latent TB) and hypersensitivity to the drug or excipients.

IL-17 Inhibitors: Secukinumab, Ixekizumab, Brodalumab, and Bimekizumab

IL-17 is a proinflammatory cytokine. It is a key cytokine in the pathogenesis of psoriasis—binding to receptors on keratinocytes leads to increased inflammation and recruitment of inflammatory cell types, resulting in the characteristic psoriatic plaques.[37]

IL-17 inhibitors are useful in blocking this process. These agents have comparable efficacies, and some adverse effects are similar, such as an increased risk of infection—in particular mucocutaneous *Candida* infection.[45] Patients with a history of or active inflammatory bowel disease (IBD) may experience worsening or reactivation, and IL-17 inhibitors should be avoided in these patients.[45] Neutralizing antibodies to specific IL-17 inhibitors have been reported, and their presence may be associated with lower serum concentrations of the biologic and reduced efficacy.[45]

Secukinumab is a fully human IgG1κ monoclonal antibody that selectively binds and inhibits IL-17A, thus inhibiting the release of chemokines and other proinflammatory mediators. It was approved in the United States and Canada in 2015 for the treatment of moderate-to-severe plaque psoriasis in adult patients who are candidates for systemic therapy or phototherapy.[45,110] The approval was based on the results of four RCTs (including ERASURE and FIXTURE)[111] that included more than 2,000 patients. Secukinumab was shown to induce a rapid response with clinically significant greater PASI rates by week 12, and continued treatment was associated with sustained high responses through week 52.[111]

The CLEAR study compared secukinumab to ustekinumab in participants with plaque psoriasis and found greater efficacy at week 16 with secukinumab.[112] Secukinumab showed greater efficacy at 300 mg than at 150 mg in several RCTs and is equally safe.[45] Thus, the recommended dosing regimen for plaque psoriasis is 300 mg (as two subcutaneous injections of 150 mg) at weeks 0, 1, 2, and 3, followed by 300 mg as a maintenance dose starting at week 4.[45,110] However, a 150-mg dose may be acceptable for some patients.[45,111] The 300-mg dose may be more effective in treating head, neck, nail, palmoplantar, erythrodermic, and generalized pustular psoriasis.[45,113–116] A loading dose may be considered for active PsA. If a loading dose is given, subsequent dosing includes 150 mg subcutaneously every week up to week 4 and then every 4 weeks thereafter. If a loading dose is not given, 150 mg subcutaneously every 4 weeks is recommended, with consideration of increasing the dose to 300 mg every 4 weeks if the disease persists, according to product labeling. Adverse effects from clinical trials commonly included nasopharyngitis, headache, upper respiratory tract infection, diarrhea, and uncommonly included neutropenia and detection of anti-secukinumab antibodies.[45,110,111]

Ixekizumab is a humanized IgG4 monoclonal antibody that neutralizes IL-17A.[45] Binding to IL-17A prevents it from binding to its target IL-17 receptor, thus reducing/attenuating the expression of cytokines including interferon-gamma, IL-17, IL-22, and Il-23.[37] It is indicated for moderate-to-severe psoriasis; pivotal clinical trials include UNCOVER-1, UNCOVER-2, UNCOVER-3, and IXORA-S.[37,45] UNCOVER-3 was a phase 3 RCT that showed that ixekizumab was superior to etanercept after a 12-week induction phase.[34,117] The percentages of patients achieving PASI 75, PASI 90, and PASI 100 were 84%, 65%, and 35% with ixekizumab versus 53%, 26%, and 7% with etanercept, respectively.[45,117] Placebo responses were 7%, 3.1%, and 0%, respectively.[117] IXORA-S was a phase 3 RCT comparing efficacy of ixekizumab with ustekinumab at the label doses. At week 12, patients achieving PASI 90 were 73% with ixekizumab versus 42% with ustekinumab.[45,118] Ixekizumab is also efficacious for palmoplantar (nonpustular), nail, scalp, erythrodermic, inverse, and generalized pustular psoriasis.[45]

Recommended dosing for ixekizumab in patients with plaque psoriasis is an initial dose of 160 mg (self-administered subcutaneously) followed by 80 mg every 2 weeks until week 12, followed by a maintenance phase of 80 mg every 4 weeks thereafter.[37,45] Dosing for active PsA is 160 mg (as two 80 mg injections) subcutaneously at week 0, then 80 mg every 4 weeks. If the patient has plaque psoriasis with active PsA, dosing for plaque psoriasis as described above is recommended. Adverse events from clinical trials include nasopharyngitis, URTI, injection site reactions, with the most serious being cellulitis (0.4%); MACE was rare (one patient with a stroke).[37] Neutralizing anti-ixekizumab antibodies develop over time and are associated with reduced drug concentrations and loss of efficacy.[45]

Brodalumab is a fully human IgG2 anti-IL-17RA monoclonal antibody that binds to the IL-17 receptor A and blocks the biologic activities of cytokines including IL-17A, IL-17F, IL-17A/F, IL-17A/F heterodimer, IL-17C, and IL-17E (also known as IL-25).[37,45] Pivotal clinical trials include IMAGINE-1, IMAGINE-2, and IMAGINE-3. In both IMAGINE-2 and IMAGINE-3, brodalumab at 210-mg doses had higher PASI 90 and PASI 100 response rates than ustekinumab.[37,45] Brodalumab is also efficacious in erythrodermic, nail, scalp, generalized pustular psoriasis, and PsA.[45] Recommended dosing is 210 mg subcutaneously self-injected on weeks 0, 1, and 2 then 210 mg every 2 weeks.[45]

The most frequent adverse effects in clinical trials of brodalumab were arthralgia, headache, fatigue, diarrhea, oropharyngeal pain, nausea, and infections were seen in 25% of patients (mostly URTI, nasopharyngitis, UTI, bronchitis, influenza, and nonserious skin and mucosal *Candida* infections).[37] The most serious potential risk is suicidal ideation or behavior which occurred in 34 of 4,464 patients treated with brodalumab (ie, a rate of 0.37 per 100 participant-years[37]). Thus, brodalumab has a black box warning, and it is contraindicated in patients with suicidal ideation, recent suicidal behavior, or history of suicidal ideation. In addition, brodalumab is only available through a risk evaluation and mitigation strategy (REMS) program,[37,45] the SILIQ REMS.[45]

imekizumab is a humanized IgG1/k monoclonal antibody that binds selectively to IL-17A, IL-17F, and IL17-AF cytokines, inhibiting their interaction with IL-17RA and IL-17RC receptors. It was approved for moderate-to-severe plaque psoriasis by Health Canada in February 2022 but had failed FDA preapproval inspection at the time of this writing. Bimekizumab has also received approval for use in psoriasis from other countries such as Japan. The Canadian approval is supported by three phase 3 trials with significant Canadian participation; these evaluated the efficacy and safety of bimekizumab compared with placebo (BE READY), ustekinumab (BE VIVID) and adalimumab (BE SURE).

Bimekizumab dosing is weight dependent, since adult patients weighing 120 kg or more are predicted to have at least 30% lower drug plasma concentrations than those weighing 90 kg. Bimekizumab is given as two 160 mg subcutaneous injections (320 mg dose) every 4 weeks for 16 weeks, followed by differential dosing based on weight: every 8 weeks thereafter EXCEPT in patients weighing 120 kg or more, for whom 320 mg every 4 weeks may be considered after week 16 if complete skin response has not been achieved.

Significant adverse reactions to bimekizumab include infections and antibody development (45%; neutralizing 16%). Recently, the two-year safety profile for bimekizumab based on pooled data from four phase 2 and phase 3 trials suggests that bimekizumab is well tolerated.[163]

IL-23 Inhibitors: Guselkumab, Tildrakizumab, Risankizumab

Acting through a transcription pathway, IL-23 induces a population of T-helper cells (designated as TH17 cells) with a unique inflammatory gene signature that is important in the pathogenesis of psoriasis and other autoimmune diseases.[119] IL-23 inhibitors block/bind to the p19 subunit of IL-23.[45] Neutralizing antibodies to specific IL-17 inhibitors have been reported and their presence may be associated with lower serum concentrations of the biologic and reduced efficacy.[45] In patients on these agents who are not responding adequately, dose escalation may be needed or other modalities (eg, TCS, vitamin D analogs, methotrexate, or UVB) added.[45]

Guselkumab is a fully human IgG1 lambda monoclonal antibody that blocks the p19 subunit of IL-23.[45] A phase 3 RCT (VOYAGE 2) comparing guselkumab with adalimumab and placebo found greater efficacy at week 16 (PASI 90 was 70% vs 47% for adalimumab and 2.4% for placebo).[120] Furthermore, 66% of adalimumab nonresponders switched to guselkumab reached PASI 90 at week 48.[45,120] The recommended guselkumab dose for active PsA and plaque psoriasis is 100 mg subcutaneously at weeks 0 and 4, and every 8 weeks thereafter.[45] The agent has also been shown to be effective for scalp, nail, and plaque-type palmoplantar psoriasis.[45]

Tildrakizumab is a humanized IgG1 monoclonal antibody designed to selectively block IL-23 by binding to the p19 subunit.[45] A phase 3 RCT (reSURFACE 2) comparing two doses of tildrakizumab (200 mg and 100 mg) to etanercept and placebo found greater efficacy at week 12 with either dose of tildrakizumab than with etanercept (66% of patients on tildrakizumab 200 mg achieving PASI 75 and 61% for tildrakizumab 100 mg, compared with 48% for etanercept and 6% with placebo).[121] PASI 90 was achieved by 37% (200-mg dose), 39% (100-mg dose), 21% (etanercept), and 1% (placebo) of participants.[45,121] The recommended dose is 100 mg subcutaneously administered *only by a healthcare provider* at weeks 0 and 4, and every 12 weeks thereafter.[45]

Risankizumab is a humanized IgG1 monoclonal antibody that selectively inhibits IL-23 by binding to the p19 subunit; it is more efficacious than ustekinumab.[45,122,123] The agent received FDA and Health Canada approvals in April 2019 for treatment of moderate-to-severe plaque psoriasis. The approval decisions were supported by positive results from four phase 3 RCTs: ultIMMa-1, ultIMMa-2, IMMhance, and IMMvent.[122,123] From clinical trials, at week 12, PASI 90 for risankizumab was about 75% (90 mg and 180 mg doses pooled) versus about 40% to 45% for ustekinumab (weight-based dosing).[45,122] Recommended dosing is risankizumab 75 mg subcutaneously for 2 doses (totaling 150 mg) at weeks 0 and 4, followed by 150 mg as two injections every 12 weeks thereafter.

Switching Between Biologic Agents

Switching between biologic agents to possibly improve efficacy, safety, and/or tolerability is a useful consideration. Biologics that develop neutralizing antibodies may have reduced efficacy over time (secondary failure),[45] and sustainability for more than 3 years is currently a treatment target for a biologic agent—and 3 years is not that long a time for a chronic disease such as psoriasis.

Switching to another biologic even within its own class of biologics may restore efficacy. However, not all switches result in improvement, and there are no recommendations for specific switches in the US guidelines, nor recommendations for the duration interval between discontinuing one biologic and starting another.[45]

BAD provided some general recommendations in its 2020 guidelines: Consider using a 1-month washout period, or the length of the treatment cycle (whichever is longer), between the last dose of the current biologic therapy and the planned date of a new biologic initiation.[44] BAD also recommended taking into consideration the pharmacology of the agents, the patient's clinical circumstances, and the patient's views on the risks and benefits of transitioning option(s).[44]

Combination Therapies

Combination therapies may be beneficial in the management of plaque psoriasis: generally to either enhance efficacy or minimize toxicity. As shown in Figs. 118-1 and 118-2, combinations can include two topical agents, a topical agent plus phototherapy, a systemic agent plus topical therapy, a systemic agent plus phototherapy, two systemic agents used in rotation, or a biologic agent with either a systemic agent or a topical agent.

The combination of a TCS and a topical vitamin D_3 analog is particularly useful. This was shown in several studies to be efficacious and safe, with less skin irritation than monotherapy with either agent, and the combination product containing calcipotriol and betamethasone dipropionate ointment has demonstrated efficacy in RCTs for patients with relatively severe psoriasis.[16,40] The combination may also be steroid sparing.[40]

The combination of retinoids with phototherapy has also been shown to increase efficacy. Because retinoids may be photosensitizing and increase the risk of burning after ultraviolet (UV) light exposure, doses of phototherapy should be reduced to minimize adverse effects. An RCT with tazarotene and broadband UVB not only showed significant enhancement of UVB efficacy but also reduced the number of UVB treatment sessions needed for response.[38,40,124] The combination of acitretin and broadband UVB reduced the number of needed treatments, compared with UVB alone.[16,125] Acitretin with NB-UVB (RE-UVB) was highly effective for patients with difficult-to-control psoriasis.[40,126] The combination of acitretin and PUVA (RE-PUVA) also showed greater efficacy than monotherapy with either agent.[38,127] RE-PUVA can be used to achieve clearance with up to a twofold reduction in total UV exposure.[16] Phototherapy has also been used with other topical agents, such as UVB with coal tar (Goeckerman regimen)[73] to increase treatment response because coal tar is also photosensitizing.

Cyclosporine and calcipotriol/betamethasone dipropionate in combination is superior to cyclosporine alone.[29] Cyclosporine may also be successfully used with SCAT; however, it should not be used with PUVA due to reduced efficacy and the potential increased risk of cutaneous malignancies.[42]

The combination of MTX and UVB is synergistic.[39,43] MTX in combination with biologics is beneficial. MTX has been effectively used in conjunction with etanercept, infliximab, adalimumab, ustekinumab, and others. MTX in combination with adalimumab or infliximab is widely used in rheumatology, and low-dose MTX (eg, 7.5-10 mg once per week) is likely sufficient to reduce the formation of anti-biologic-antibodies and increase the respective trough levels of adalimumab or infliximab.[29] Infliximab given concurrently with MTX or azathioprine may result in a lower incidence of infusion reactions to infliximab.[41]

Biologics used in combination with nonbiologic therapies are being explored and recommended, sometimes with just a theoretical rationale (ie, without RCT backup yet). In particular, the concept of increasing biologic survival with the addition of an immunosuppressive agent that reduces the development of neutralizing biologic antibodies is gaining acceptance as experience and clinical evidence accumulate with their use. Newer biologics whose use is associated with neutralizing antibodies are often used together with an immunosuppressive agent such as MTX.[45]

Other Drug Treatments

Selective Phosphodiesterase-4 (PDE4) Inhibitors: Crisaborole, Apremilast

A relatively new approach to management of inflammatory skin conditions such as psoriasis and atopic dermatitis (AD) is targeted inhibition of phosphodiesterase 4 (PDE4).[128] PDE4 inhibition causes an increase in intracellular cyclic AMP (cAMP), which leads to multiple effects, including reduced production of proinflammatory mediators.[128]

Apremilast is an oral tablet approved in the United States and Canada for patients with active PsA or moderate-to-severe psoriasis. It has shown efficacy and safety in 2 Phase III RCT (ESTEEM 1 and ESTEEM 2) for patients with psoriasis.[129] Recommended dosing is 10 mg on day 1, 10 mg twice daily on day 2, 10 mg in the morning and 20 mg in the evening on day 3, 20 mg twice daily on day 4, 20 mg in the morning, and 30 mg in the evening on day 5, then 30 mg twice daily thereafter. Dosing if renally impaired (CrCl <30 mL/min [0.5 mL/s]) is 10 mg in the morning on days 1 to 3; titrate using morning doses only (skip evening doses) to 20 mg on days 4 and 5, with the maintenance dose of 30 mg once daily in the morning thereafter.

Apremilast may be taken without regard to food; however, it should not be crushed, chewed, or split. There are drug interactions: the levels/effects of apremilast may be decreased by bosentan, CYP3A4 inducers (moderate and strong); dabrafenib, deferasirox, ivosidenib, lorlatinib, pitolisant, sarilumab, siltuximab, tocilizumab, and St. John's wort.[130]

Crisaborole is a topical PDE4 inhibitor approved for atopic dermatitis.

Mycophenolate Mofetil

Mycophenolate mofetil (MMF) is a systemic agent occasionally used for patients with resistant cases of moderate-to-severe psoriasis.[16] This is not an approved indication in either Canada or the United States (off-label use).

A few reports and small studies are available describing the efficacy of MMF when used as monotherapy or adjuvant therapy.[131] In addition, one small study evaluated the switch for eight patients with severe psoriasis from cyclosporine to MMF after a washout period of 2 to 4 weeks. On cyclosporine, seven of these patients had deteriorating renal function and hypertension, and one experienced loss of efficacy.[132] After the switch to MMF, there was a significant loss of psoriasis control in five of the eight patients, but also a significant improvement in renal function for six patients.[131,132]

Conversely, another small study evaluated the sequential use of MMF followed by cyclosporine in eight patients with moderate-to-severe psoriasis.[133] There was significant improvement with MMF in all patients, and all patients further improved when switched to cyclosporine.[133]

MMF has some uncommon but significant adverse effects, including increased incidence of opportunistic infections such as cytomegalovirus, cryptococcosis, candidiasis, and *Pneumocystis jirovecii*.[3,131] Cases of progressive multifocal leukoencephalopathy have also been reported.[131] There may be an associated risk of malignancy.[134]

Hydroxyurea

Hydroxyurea is an antimetabolite usually used for cancer treatments, but it has also been used in the systemic treatment of psoriasis for more than 30 years.[16,39] It is still occasionally tried for patients with recalcitrant severe psoriasis, although biologics may be a better option for these patients.

Hydroxyurea has been compared with MTX for patients with moderate-to-severe psoriasis.[135] Weekly regimens showed greater efficacy for MTX with a faster clearance rate, although hydroxyurea was also efficacious. The authors concluded that weekly doses of hydroxyurea may be an alternative to MTX for patients experiencing intolerable MTX side effects or who have reached the recommended cumulative MTX dose.[135]

Adverse effects of hydroxyurea include significant bone marrow suppression, lesional erythema, localized tenderness, and reversible hyperpigmentation.[16,135]

Complementary and Alternative Medicines

The use of complementary and alternative medicine (CAM) among patients with psoriasis is common, with a prevalence of 43% to 69% in various studies.[136] Most of these patients use herbs, special diets, or dietary supplements in conjunction with their usual antipsoriatic medications and not as replacements. Most patients do not discuss CAM use with their physicians.[136]

A 2009 systematic review of RCTs found that, although there is a large body of literature on CAM use in psoriasis, the quality of most studies was relatively low.[136] CAM agents and interventions with documented clinical efficacy in psoriasis include *Mahonia aquifolium*, fish oil, climatotherapy (Dead Sea salts), and stress reduction techniques.

Mahonia aquafolium (Oregon grape, Mountain grape, or barberry but *not* European barberry) is an evergreen native to southern British Columbia, western Oregon, and northern Idaho. The rhizome and root contain berberine as the primary active constituent. Berberine is an alkaloid that inhibits keratinocyte growth and reduces keratinocyte proliferation, and it also has antibacterial and antifungal activities. In at least two clinical trials, *Mahonia aquifolium* was efficacious in reducing disease severity: in one randomized placebo-controlled study, a *Mahonia aquifolium* 10% preparation applied topically twice daily resulted in a significant improvement in the PASI score and the Quality of Life Index (QLI), compared with placebo.[137] Adverse effects in clinical trials included rash, burning sensation, redness, and itching.

Fish oil contains two important long-chain polyunsaturated fatty acids—eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). EPA and DHA are omega-3 fatty acids. They act as substrates competing with arachidonic acid for cyclooxygenase and lipoxygenase, thus reducing the production of proinflammatory molecules in psoriatic plaques.[136] Several randomized placebo-controlled and/or comparative trials for patients with psoriasis have demonstrated efficacy of fish oils. One study comparing EPA plus etretinate to etretinate monotherapy found significantly greater efficacy with the combination of EPA plus etretinate.[138]

Climatotherapy refers to the practice of traveling to the Dead Sea and sunbathing and/or bathing in the sea—the beneficial effects are likely from the high salinity of the sea and UV rays.[136] Several studies have demonstrated efficacy, including two studies using saline spa baths. One study used highly concentrated (25%-27%) saline spa baths plus UVB compared with UVB alone, and the other used low concentrated (4.5%-12%) saline spa bath plus UVB again compared with UVB alone. In both studies, the clinical response was significantly better with the saline spa bath plus UVB combination.[136,139,140]

Stress-reduction techniques have inconsistently shown some benefit. One randomized study demonstrated that both meditation or meditation and imagery were efficacious as adjunctive treatments for patients with scalp psoriasis.[141] A second randomized study for patients with psoriasis receiving either UVB or PUVA therapy showed that the addition of a mindfulness-based stress-reduction audiotape played during light treatments reduced response times for patients receiving UVB but not PUVA therapy.[142] This confirmed the belief that psychological stress plays a role in psoriasis. More recently, in a case-control study of risk factors during the year before the onset of psoriasis, stressful life events were found to be significant.[143,144]

Personalized Pharmacotherapy

Despite the availability of good quality evidence and clinical practice guidelines, patients with psoriasis are still often undertreated or inappropriately managed.[30] A 2007 study in the United States involving 1,657 patients from National Psoriasis Foundation surveys found that 40% of patients with psoriasis were receiving no current treatment; of those, 27% had psoriasis involving >10% BSA.[145] In addition, those receiving care may be undertreated.[145] Early access to care and adherence may also be issues.

Patient-specific therapies that take into consideration comorbid illnesses, adherence, and pharmacoeconomic issues in addition to the patient’s psoriatic manifestations and responses to treatments are important, and will ultimately improve the quality of care. Treatment goals need to be patient-specific and defined for both short-term and long-term management time frames.[30] Without optimizing patient care, the concern is that patients with poorly managed psoriasis may follow a “diminished” life course compared with the course they might have taken if they did not have psoriasis, as the disease has significant psychological, social, and economic impacts in addition to its physical manifestations.[146]

To this end, a current focus is defining frameworks,[146] specific treatment goals,[29,30] and targets[31] for implementation of practice guidelines, as described earlier in this chapter. The reader is encouraged to review the noted references for further information.

Special Populations

Psoriasis in Children

Psoriasis affects approximately 1% of children, with the most common onset during adolescence. One third of patients with psoriasis had onset of symptoms during the pediatric years.[147] Psoriasis in infants is uncommon, but it does occur.[147] Pediatric psoriasis is more often attributable to direct precipitating factors such as skin trauma, infections, drugs, or stress.[16,148] Compared with adults, plaque lesions in children are often smaller, thinner, and less scaly, which can make diagnosis more difficult. Face and flexures are more commonly involved than for adults. Psoriatic diaper rash can occur up to age 2. PsA is rare.[16]

Disease severity in clinical practice is most often defined using the percentage of BSA that is affected: less than 3%, mild; 3%-10%, moderate; and more than 10%, severe. The 2020 AAD-NPF guidelines of care for psoriasis in pediatric patients state that BSA should not be the sole predictor of disease severity, and that the impact on the child’s QoL should be taken into consideration. For example, a child with psoriasis limited to the face or scalp may not have severe disease based on BSA definitions, but if the skin involvement has led to social withdrawal, shame, or bullying by others, it could be considered severe based on impact beyond the skin. A 2020 Canadian consensus concurs that children with psoriasis may experience stigmatization, social isolation affecting emotional and/or social development, and changes in their school functioning. Stigmatization may result in depression, anxiety, eating disorders, and risk-taking behaviour. A Children’s Dermatology Life Quality Index (CDLQI) derived from the DLQI used in adults to assess QoL for patients age 4 through 16 years is available in written and cartoon form.[86,147]

Psoriasis in children is associated with cardiovascular risk factors and metabolic syndrome.[16] Cardiovascular risk factors include being overweight, obesity, hyperlipidemia, hypertension, high blood glucose, and diabetes.[16] Obesity and excessive waist circumference (central adiposity) are higher in children with severe psoriasis, and in general, are higher in childhood psoriasis than in adults.[16,149] Adolescent girls who are overweight are at increased risk of later developing moderate-to-severe psoriasis, suggesting that obesity precedes the onset of psoriasis.[16,150]

Thus, nonpharmacologic management strategies in children also include minimizing cardiovascular risk factors and the development of the metabolic syndrome. The importance of maintaining a healthy lifestyle with good eating habits, exercise, and weight balance is crucial information to communicate to the child/adolescent and caregivers.

Topical treatment is the standard-of-care for children with psoriasis.[16,151] Vitamin D3 analogues (calcipotriene, calcipotriol, and calcitriol) have a corticosteroid-sparing function; this is an important advantage for pediatric patients. Calcipotriol with or without TCS has been recommended as treatment of first choice[16,151] because it produces minimal adverse effects.[16] Since children's skin is thinner and better hydrated than that of adults, they are at higher risk of drug absorption leading to systemic adverse effects. If a TCS is needed, the lowest potency TCS that provides control should be used, and it should be tapered as the lesions improve.

Combination products with calcipotriol and betamethasone dipropionate are effective and have FDA approval for use in children 12 years and older. Calcipotriol/betamethasone dipropionate ointment applied once daily for up to 4 weeks at a time has been recommended by AAD-NPF as a safe and effective treatment for children 12 years and older with mild-to-moderate plaque psoriasis, and the suspension has been recommended for once-daily use up to 8 weeks for mild-to-moderate scalp psoriasis. Due to the expense of combination products, individual products are often prescribed for simultaneous use in various regimens (e.g. once daily for the first 2 weeks, then reduced to weekends for topical corticosteroids and weekdays for the vitamin D analogue). To minimize corticosteroid use, combination therapy can be transitioned to topical vitamin D monotherapy when the condition improves.[147]

If long-term calcipotriol is used, monitoring of ionized calcium is recommended because of the risk of hypercalcemia.[16] Topical calcineurin inhibitors have been recommended as first-line therapy for psoriasis of the face, genitalia, and body folds. Rotational therapy with topical vitamin D analogues, topical calcineurin inhibitors, emollients, tar-based therapies, and topical corticosteroids should be considered in children as steroid-sparing regimens.[147,151]

For treatment-resistant or moderate-to-severe psoriasis, anthralin has been suggested, before considering short-term UVB in adolescents.[16,151] NB-UVB is recommended as a treatment option for moderate-to-severe pediatric plaque and guttate psoriasis.[147]

Systemic therapies (traditional nonbiologic and biologic) are appropriate for children with moderate-to-severe and recalcitrant psoriasis[16,86,147,151] or in the presence of comorbidities such as psoriatic arthritis.[147] In general, the goal with all systemic therapies in children is to control or clear the disease, provide maintenance disease stability for several months, then taper to the lowest effective dose and ultimately transition off systemic therapies if possible. If not possible, long-term maintenance at the lowest effective dose using the least toxic therapy is the preferred approach. MTX can provide near to complete clearance and has been recommended as the systemic treatment of choice in the Canadian guidelines[16] and recommended as effective systemic therapy in the AAD-NPF guidelines. MTX can be safely used to control severe childhood psoriatic episodes and then withdrawn as lesions improve.[16] Folate supplementation is recommded. Regular monitoring for liver and blood toxicity is required.16 Other nonbiologic systemic agents such as cyclosporine and acitretin may also be used in children.[86,147]

Biologic agents recommended in the 2020 AAD-NPF guidelines for use in children include etanercept, adalimumab, infliximab, and ustekinumab.[147] Etanercept has been recommended as a third-line option in the 2016 Canadian guidelines.[16] A 2020 Canadian consensus summarizing the most recent evidence on the use of biologics for moderate-to-severe plaque psoriasis in pediatrics provides an algorithm that includes the biologics etanercept, adalimumab.[86] A randomized controlled trial in 211 children and adolescents (4-17 years) with moderate-to-severe plaque psoriasis showed that etanercept significantly reduced disease severity; however, four serious adverse events occurred (ovarian cyst requiring removal, gastroenteritis, gastroenteritis-associated dehydration, and left basilar pneumonia).[148] Etanercept has been studied in children with polyarticular juvenile rheumatoid arthritis without new safety concerns emerging.[16] Ustekinumab and adalimumab's safety profiles are also continuing to be evaluated.[16]

Biologics can be safely combined with topical corticosteroids, with or without a topical vitamin D analogue, to augment effectiveness for the treatment of moderate-to-severe plaque psoriasis in children.147

Phototherapy should be used with caution, especially for younger children, because of long-term carcinogenic risks and phototoxicities. For older children and adolescents with severe, extensive, or treatment-resistant disease, UVB (in particular, NB-UVB) may be a treatment option.[16]

Psoriasis in Pregnancy

Hormonal changes in pregnancy can improve symptoms for patients with plaque psoriasis. In one study, 55% of patients showed improvements during pregnancy.[16,153] For patients with more than 10% BSA involvement who reported improvement, lesions decreased by more than 80% during pregnancy.[153] This appeared to correlate with high estrogen but not progesterone levels.[153] Thus, some pregnant women may require minimal treatment for their psoriasis.

Some antipsoriatic drugs have significant teratogenic risks, making them contraindicated in pregnancy. Thus, women of childbearing potential must use effective birth control during therapy, and may need to continue effective contraception after discontinuing therapy for a period of time, as discussed in detail throughout this chapter. In addition, some drugs may carry known teratogenic risks in animal studies or have limited available data for use in pregnancy in humans.

UVB has been considered the safest treatment for extensive psoriasis during pregnancy. It is recommended for patients with widespread disease not controlled by topical agents. One problem with this therapy is an increased potential for reactivation of herpes simplex, which may be transmitted to the infant at delivery.[16]

For more detailed information about antipsoriatic drugs in pregnancy, a systematic, drug-by-drug review of case reports and case-control studies is available.[154] The 2009 Canadian Guidelines provides a drug-by-drug summary of recommendations for topical agents, phototherapy, and systemic agents in pregnancy.[16] The 2015 European S3 Guidelines provides a discussion about most appropriate treatments for women with a wish for pregnancy in the near future, and which treatments to avoid.[29]

Psoriasis in Older Adults

Age-related changes in organ function/drug clearance and greater drug sensitivity increase the risk of adverse drug events for elderly patients with psoriasis.

MTX is hepatotoxic and should be used with caution in older adults. Cyclosporine has nephrotoxic potential and may also increase blood pressure. Both drugs have significant drug interactions, and polypharmacy, common in older patients, makes management of interactions challenging.

In addition, older patients may have preexisting comorbidities, such as hyperlipidemia and metabolic syndrome, and this may further limit drug selection. Adalimumab is equally efficacious in patients aged 65 years or older who may have higher incidences of hypertension, hyperlipidemia, depression, obesity, and diabetes.[155] Adverse-effect profiles were similar between subgroups (various weights and comorbidities) with no significant differences in serious adverse events.[155] Ustekinumab requires no dosage adjustments for renal or hepatic impairments and geriatric dosing is the same as for adults younger than 65 years, with the dose based on weight. Secukinumab also requires no dosage change in older adults and those with renal/hepatic impairment.

Topical psoriasis treatments are often prescribed for older adults as first-line therapy[16]; however, even with topicals, adverse effects—including systemic ones—can occur with greater frequency in these patients.[16]

Psoriasis in Patients with a History of Solid Tumors

As discussed throughout this chapter, many antipsoriatic therapies carry significant cancer risks. PUVA, systemic therapies such as cyclosporine, and some biologics are associated with increased risks of oncologic disorders.

A systematic review of the risk of malignancy associated with therapies for moderate-to-severe psoriasis confirmed the following[134]: PUVA is associated with an increased risk of cutaneous SCC and malignant melanoma; UVB is a much safer therapeutic modality than PUVA; cyclosporine increases risks of lymphoma, internal malignancies, and skin cancers; methotrexate may be associated with increased melanoma and Epstein-Barr virus–associated lymphomas; MMF may be associated with lymphoproliferative disorders; and the malignancy risk may be increased for biologic agents, especially the TNF-α inhibitors.[134]

The 2009 Canadian guidelines recommend that TNF-α inhibitors be used with caution for patients with a history of malignancy or existing malignancies, and the T-cell modulator alefacept (now voluntarily withdrawn from the US and Canadian markets) is contraindicated for these patients.[16] There are currently registry safety databases (PSOLAR,[156] BADBIR,[157] PsoBest[158,159]) for biologics; over time, these will provide biologic-specific and updated safety information.[159] Known risks in general include the development of neoplasms such as nonmelanoma skin cancer.[89]

Coronavirus Disease 2019 Risk in Patients Receiving Biologics for Psoriasis

During the coronavirus disease 2019 (COVID-19) pandemic caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), there was concern around increased risk of infection in patients receiving ongoing biologic therapy for psoriasis.

A study exploring the incidence of COVID-19 in 1,830 patients with psoriasis who were receiving various biologics (etanercept, ustekinumab, ixekizumab, secukinumab, and guselkumab) found a COVID-19 incidence rate (IR) of 9.7 (95% CI 3.9-20.1) per 10,000 person-months in patients with psoriasis versus an IR of 11.5 (95% CI 11.4-11.7) per 10,000 person-months in the general population. This study was conducted in northeast Italy (the Veneto region comprising Verona, Padua, and Vicenza) with data collected between February 20, 2020, and June 1, 2020, during the height of an initial wave of the COVID-19 pandemic in this region. Only six cases of COVID-19 occurred among 1,830 patients with psoriasis compared with 19,154 cases among 4,905,854 people in the general population. Of the six COVID-19–positive patients with psoriasis, four were hospitalized with interstitial pneumonia with no deaths. These results were contrary to the expectation that the incidence and severity of COVID-19 would be higher in patients with psoriasis as they had a higher prevalence of known comorbidities (hypertension, cardiovascular diseases, diabetes) than those in the general population.[160]

Pharmacoeconomic Considerations

⑩ The wide gap in costs of agents for psoriasis makes economics and availability of insurance or other coverage important considerations in formulating a therapeutic plan.

The biologics are often considered for patients with moderate-to-severe psoriasis when less-expensive traditional systemic agents are inadequate or relatively contraindicated. Biologics have also been recommended as first-line therapy, alongside conventional systemic agents, for patients with moderate-to-severe psoriasis; however, in practice, drug access secondary to cost considerations can limit use. These agents may be needed early, though, for some patients with comorbidities, such as PsA.

A pharmacoeconomic analysis of biologics in the treatment of psoriasis suggests that the cost-to-benefit ratio for biologics may be favorable.[161] This analysis was performed in 2009 when available biologics were fewer and more expensive than today. More recent analyses indicate wide variations when clinical outcomes are factored into costs of recently marketed agents.[162]

CONCLUSION

Psoriasis is a lifelong illness with no known cure. Significant comorbidities may coexist. Treatment should be patient-specific, with consideration given to disease severity, patient risk factors, age, and comorbidities. Newer treatment modalities, including numerous biologics, are now parts of the armamentarium available in the management of this disease.

ABBREVIATIONS

BAD	British Association of Dermatologists
BADBIR	British Association of Dermatologists Biologic Interventions Register
BMI	body mass index
BRM	biologic response modifier (This term has been replaced by “biologic agents.”)
BSA	body surface area
CAM	complementary and alternative medicine
CDA	Canadian Dermatology Association

CHD	coronary heart disease
CHF	chronic heart failure
COVID-19	Coronavirus Disease 2019
CRP	C-reactive protein
CYP3A4	cytochrome P450 isoenzyme 3A4
DBPC	double-blind placebo-controlled
DHA	docosahexaenoic acid
DISH	disseminated (or diffuse) idiopathic skeletal hyperostosis
DLQI	Dermatology Life Quality Index
EPA	eicosapentaenoic acid
FDA	Food and Drug Administration
GFR	glomerular filtration rate
HLA-C	major histocompatibility complex antigen
HPA	hypothalamic–pituitary–adrenal
IL	interleukin
MACE	major adverse cardiovascular events
MMF	mycophenolate mofetil
MI	myocardial infarction
NPF	National Psoriasis Foundation
NSAIDs	nonsteroidal anti-inflammatory drugs
NB-UVB	narrowband ultraviolet B (311-nm ultraviolet B light)
OR	odds ratio
PASI	Psoriasis Area and Severity Index
PGA	Physician’s Global Assessment
PsA	psoriatic arthritis
PUVA	psoralens with ultraviolet A light

QoL	quality of life
QLI	Quality of Life Index
RCT	randomized controlled trial
RE-PUVA	retinoid plus PUVA (as combination therapy)
RE-UVB	retinoid plus NBUVB (as combination therapy)
RPLS	reversible posterior leukoencephalopathy syndrome
RR	relative risk
SARS-COV2	severe acute respiratory syndrome coronavirus
SCAT	short-contact anthralin therapy
SCC	squamous cell carcinoma
SF-36	Short Form Health Survey
SPF	sun protection factor
TB	tuberculosis
TNF-α	tumor necrosis factor-α
UV	ultraviolet
UVA	ultraviolet A (315-400 nm ultraviolet A light)
UVB	ultraviolet B, or broadband UVB (28-315 nm ultraviolet B light)

SELF-ASSESSMENT QUESTIONS

1. Which of the following may precipitate new-onset psoriasis?

    A. Corticosteroids

    B. Azathioprine

    C. β-Adrenergic blocker

    D. Thiazide diuretics

2. Which of the following may exacerbate preexisting psoriasis?

    A. β-Adrenergic blocker

    B. Lithium

    C. Nonsteroidal anti-inflammatory drugs

    D. All of the above

3. Comorbidities associated with psoriasis include all of the following except:

    A. Psoriatic arthritis

    B. Crohn’s disease

    C. Multiple sclerosis

    D. Multiple myeloma

4. A 33-year-old man has been diagnosed with mild plaque psoriasis. Presenting clinical signs and symptoms may include all of the following except:

    A. Hypopigmentation

    B. Pruritus

    C. Erythema

   D. Silvery scales on lesions

5. True or false: Psoriasis is an independent risk factor for artherosclerosis.

   A. True

   B. False

6. True or false: Psoriasis is usually diagnosed based on a skin biopsy.

   A. True

   B. False

7. Appropriate nonpharmacologic therapy for a 33-year-old person with mild plaque psoriasis includes all of the following except:

   A. Moisturizer applied ad lib

   B. Oatmeal baths

   C. Tanning beds

   D. Stress management clinics

8. Initial pharmacologic therapy for a 33-year-old person with mild plaque psoriasis should be:

   A. Betamethasone dipropionate 0.05% ointment for 2 months

   B. Calcipotriol 50 µg/g cream for 2 months

   C. Methotrexate 5 mg/week for 2 months

   D. PUVA treatments for 2 months

9. SCAT therapy refers to:

   A. Steroid + plus calcipotriol use

   B. Steroid + pluscoal tar use

   C. Anthralin use

   D. Tazarotene use

10. A 28-year-old person is in the first trimester of pregnancy. She has severe plaque psoriasis that did not improve when she became pregnant. In fact, the stress of pregnancy has resulted in a flare-up of her psoriasis. Appropriate treatment for this person's psoriasis would be:

    A. Methotrexate

    B. NB-UVB

    C. Topical tazarotene

    D. Acitretin

11. Moderate-to-severe psoriatic lesions in a 33-year-old person fail to clear with topical therapy or NB-UVB. The NB-UVB treatments were continued and acitretin was added. Appropriate counseling for this patient includes all of the following except:

A. Effective birth control for the duration of acitretin therapy.

B. Effective birth control for at least 2 years after discontinuing acitretin.

C. Ineligible to donate blood.

D. No more than two alcoholic drinks per day.

12. Moderate-to-severe psoriatic lesions in a 48-year-old person are being treated with methotrexate. Although rare, pancytopenia can occur anytime—even after single doses of methotrexate. The patient should be counseled about the early signs and symptoms of pancytopenia, which include:

A. Stomatitis/oral symptoms

B. Fever

C. Dyspnea/cyanosis

D. All of the above

13. Initial biologic selection for a patient with moderate-to-severe psoriasis who also has active psoriatic arthritis (as recommended by both the Canadian Psoriasis Guidelines Addendum Committee and the British Association of Dermatologists) is:

A. Methotrexate

B. Adalimumab

C. Tildrakizumab

D. Tofacitinib

14. The systemic treatment of choice for children with severe psoriasis is currently:

A. Acitretin

B. Methotrexate

C. Cyclosporine

D. Prednisone

15. Precautions about the use of apremilast include all of the following except:

A. Take with food

B. Do not crush, split or chew the tablet

C. Drug interaction with St. John's wort

D. Dose reduction in renal impairment

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** Of these options, only beta-blockers are precipitating factors for psoriasis.
2. **D.** All of the listed options can exacerbate psoriasis.
3. **D.** Multiple myeloma is not associated with psoriasis.

4. **A.** The psoriatic plaques are red-violet and sharply demarcated from normal skin. Hypopigmentation is not consistent with psoriasis.
5. **A.** This is true. Psoriasis is an independent risk factor for atherosclerosis, especially for younger patients with severe disease. This leads to increased cardiovascular mortality risk.
6. **B.** This is false. Psoriasis is diagnosed based on clinical presentation: recognition of the characteristic psoriatic lesion, and not on laboratory tests.
7. **C.** Tanning beds are inappropriate for treatment of psoriasis.
8. **B.** The patient has mild psoriasis, which can be appropriately treated with calcipotriol topically as initial therapy. The betamethasone dipropionate 0.05% ointment is too potent, and systemic therapy with methotrexate or phototherapy is inappropriate as initial therapy for mild plaque psoriasis.
9. **C.** SCAT therapy refers to Short Contact (20 minutes to 2 hours) Anthralin Therapy, using a much higher anthralin concentration and is meant for thicker plaques such as may be found on knees and elbows.
10. **B.** NB-UVB is safe to use in pregnancy. The other three listed choices are teratogenic.
11. **D.** This person should avoid alcohol during therapy and for 2 months after drug discontinuation, as alcohol causes transesterification of acetretin to etretinate, which has a much longer elimination half-life.
12. **D.** Early signs and symptoms of pancytopenia may be nonspecific and includes all the above.
13. **B.** A TNF or IL-17 antagonist is recommended as first-line biologic therapy in patients with moderate-to-severe psoriasis who also have active PsA. Adalimumab is a TNF inhibitor and is the best option to use for comorbid active PsA. Methotrexate is not a biologic agent. Tildrakizumab is an IL-23 antagonist and is not indicated for active PsA. Tofacitinib is an oral JAK inhibitor approved for active PsA, however, is not a biologic agent. There are no IL-17 antagonists available as answer options.
14. **B.** Methotrexate has been recommended as the systemic treatment of choice and can be safely used to control severe childhood psoriatic episodes and then withdrawn as lesions improve. Regular monitoring for liver and blood toxicities is required.
15. **A.** Apremilast may be taken without regard to food.

Chapter 119: Atopic Dermatitis

Rebecca M. Law; Wayne P. Gulliver

KEY CONCEPTS

KEY CONCEPTS

① Atopic dermatitis is a chronic skin disorder involving inflammation associated with intense pruritus (itching), a hallmark symptom. Management of atopic dermatitis must always include appropriate management of the associated pruritus.

② Atopic dermatitis is associated with other atopic diseases such as asthma and allergic rhinitis in the same patient or family. The three conditions are known as the *atopic triad*.

③ The prevalence of atopic dermatitis has increased two- to threefold in many developed and developing countries during the past three decades. Age and country or regional differences, with some countries, show no change or even a decrease. Rural areas have lower prevalence rates.

④ There are genetic and environmental factors in the pathogenesis and pathophysiologic manifestations of atopic dermatitis. The inheritance pattern is not straightforward. More than one gene may be involved in the disease, with the filaggrin gene (*FLG*) being a key player. Other genes coding for specific cytokines are also involved.

⑤ Atopic dermatitis usually presents in infants and young children. The clinical presentation differs somewhat depending on the age of the patient.

⑥ Disease severity can be determined by using SCORAD (Severity Scoring of Atopic Dermatitis). This composite index assesses both signs and symptoms to classify overall disease severity as mild, moderate, or severe, which is useful in determining appropriate treatment approach.

⑦ Secondary bacterial skin infections are common in patients with atopic dermatitis and must be promptly treated.

⑧ Management of atopic dermatitis must always include appropriate nonpharmacologic management of any controllable environmental factors, such as avoidance of identified triggers. These may include aeroallergens (eg, mold, grass, pollen), foods (eg, peanuts, eggs, tomatoes), chemicals (eg, detergents, soaps), clothing material (eg, wool, polyester), temperature (eg, excessive heat), and humidity (eg, low humidity).

⑨ Nonpharmacologic management of atopic dermatitis entails managing the symptoms associated with pruritus and encouraging appropriate skin care habits such as proper bathing techniques and the copious use of moisturizers, which is a standard of care.

⑩ Topical corticosteroids (TCS) are the drugs of first choice for atopic dermatitis.

⑪ Topical calcineurin inhibitors (TCI), that is, tacrolimus and pimecrolimus, are alternate treatment options for adults and children over the age of 2 years.

⑫ Phototherapy is a second-line treatment when TCS and TCI fail.

⑬ Biologic agents and JAK inhibitors may be an option for severe atopic dermatitis in adults and adolescents (not approved in children).

⑭ This chronic illness has substantial socioeconomic impact. The burden of disease is significant, and the societal cost is magnified by undertreatment.

BEYOND THE BOOK

BEYOND THE BOOK

Some of the treatment modalities for atopic dermatitis are also used in psoriasis. Review the discussion about topical corticosteroids (including the corticosteroid potency chart) in Chapter 118, “Psoriasis,” in this textbook.

INTRODUCTION

① Atopic dermatitis (AD) is a chronic, pruritic inflammatory skin disease. It is often referred to as *eczema*, which is a general term for several types of skin inflammation. AD is the most common type of eczema (Table 119-1).[1] Pruritus is the hallmark symptom and presentation and is responsible for much of the disease burden borne by patients and their families.[2]

TABLE 119-1

Types of Eczema (Dermatitis)

- **Allergic contact eczema (dermatitis):** A red, itchy, weepy reaction where the skin has come into contact with a substance that the immune system recognizes as foreign, such as poison ivy or certain preservatives in creams and lotions.
- **Atopic dermatitis:** A chronic skin disease characterized by itchy, inflamed skin.
- **Contact eczema (dermatitis):** A localized reaction that includes redness, itching, and burning where the skin has come into contact with an allergen (an allergy-causing substance) or with an irritant such as an acid, cleaning agent, or other chemical.
- **Dyshidrotic eczema:** Irritation of the skin on the palms of hands and soles of the feet characterized by clear, deep blisters that itch and burn.
- **Neurodermatitis:** Scaly patches of the skin on the head, lower legs, wrists, or forearms caused by a localized itch (such as an insect bite) that become intensely irritated when scratched.
- **Nummular eczema:** Coin-shaped patches of irritated skin—most common on the arms, back, buttocks, and lower legs—that may be crusted, scaling, and extremely itchy.
- **Seborrheic eczema:** Yellowish, oily, scaly patches of skin on the scalp, face, and occasionally other parts of the body.
- **Stasis dermatitis:** A skin irritation on the lower legs, generally related to circulatory problems.

Data from Reference 1.

② This form of dermatitis is commonly associated with a personal or family history of other atopic disorders, such as allergic rhinitis and asthma[2] (collectively known as the *atopic triad*). AD has been considered the start of the “atopic march”[2]; however, the association with other atopic conditions is multifactorial and complex since this progression does not happen in all cases.[2] The disease can have periods of exacerbation, or flare-ups, followed by periods of remission. These flare-ups may be disruptive to the patient’s quality of life and may affect the entire family. Disease flare-ups may be difficult to manage and may be complicated by secondary infections. About one-half (estimate up to 65%) of cases in children first manifest before the age of 1 year[1–4]; these cases are termed *early onset atopic dermatitis*.[3,5] Onset of AD is most common between 3 and 6 months of age.[2] Approximately 85% to 90% of patients develop symptoms before the age of 5 years.[2]

About 10% to 30% of children with AD will have the same skin condition continuing into their adulthood.[2] Early and severe onset, family history of AD, and early allergen sensitizations are risk factors for a prolonged course.[3] Furthermore, patients who have apparently outgrown their disease may continue to have sensitive hyper-reactive skin and might have recurrences after long symptom-free periods.[3] However, onset after the age of 30 years is much less common and is often caused by exposure to harsh or wet conditions[1] such as repeated skin trauma or exposure to harsh chemicals.

EPIDEMIOLOGY

③ The prevalence of AD is generally said to have increased two- to threefold in developed and developing countries during the past three decades.[5] In developed countries, an estimated 15% to 30% of children and 2% to 10% of adults are affected.[3,5,6] The prevalence has increased worldwide, as earlier prevalence rates were estimated at 10% to 15% in children.[4] In developed countries, the lifetime prevalence seems to have plateaued at 10% to 20%, whereas in many developing countries, the lifetime prevalence may be lower but continues to increase.[3]

③ The largest international study of the prevalence of AD found both age and country differences in prevalence rates.[7] This was the International Study of Asthma and Allergies in Childhood (ISAAC), which was conducted in three phases.[8] The strength of this study was the use of a uniformly validated methodology that allowed a direct comparison of results from pediatric populations worldwide.[9] ISAAC Phase One included 700,000 children from 156 centers in 56 countries between 1992 and 1998. ISAAC Phase Two studied allergic causes from 30 centers in 22 countries. ISAAC Phase Three repeated a multicountry cross-sectional survey (1999–2004) and included 187,943 children aged 6 to 7 years from 64 centers in 35 countries and 302,159 adolescents aged 13 to 14 years from 105 centers in 55 countries. For children aged 6 to 7 years, most countries showed an increase of two standard deviations (SDs) in mean annual prevalence over a 5- to 10-year period. In contrast, for adolescents aged 13 to 14 years, the trends differ from country to country. Large increases in prevalence were seen in developing countries (eg, Mexico, Chile, Kenya, and Algeria, and seven countries in Southeast Asia). But in other countries with formerly high prevalences, the mean annual prevalence in eczema symptoms has either leveled off or decreased. Most of the largest decreases (SD ≥2) in prevalence were reported from developed countries in northwest Europe (eg, the United Kingdom, Ireland, Sweden, Germany) and New Zealand.[7] The ISAAC study has suggested that a maximum prevalence plateau of approximately 20% has emerged.[7,8]

There were no differences according to the sex of the study participant, or with gross national income at a country level.[7] This is consistent with other reports that AD affects males and females at approximately the same rate.[1] There is a lower prevalence of AD in rural areas when compared with urban areas,[2] suggesting a link to the *hygiene hypothesis*,[10,11] which postulates that the absence of early childhood exposure to infectious agents increases susceptibility to allergic diseases.[10–12] In contrast, children attending daycare centers before 3 months of age have less atopy and asthma in later childhood,[11,12] and areas with diffuse and chronic helminth infestations have a low prevalence of allergic diseases.[12] In addition, a European birth cohort study involving 1,133 newborns showed that children born to farm families had a lower prevalence of sensitization to seasonal inhaled allergens such as grass pollen.[11,13] Maternal exposure during pregnancy (ie, prenatal exposure) to animal sheds correlated with the lower prevalence rate in the farm children. However, there were no differences in prevalence related to inhaled perennial allergens. Parasitic infections decreased the risk of allergen sensitization.[11] A systematic review reported that exposures to endotoxin, farm animals, and dogs may protect against AD.[14]

Reported risk factors associated with higher prevalence include urban environment, higher socioeconomic status, higher level of family education, a family history of AD, female gender (after age 6 years), and smaller family size.[8] However, more recent studies are conflicting. There are no consistent findings that higher socioeconomic status or male/female gender affect the risk of AD.[2] Urban living does increase the risk of AD, but studies attempting to identify causative environmental agents have been inconclusive.[2] Strongly associated risk factors include a family history of AD, and functional mutations in the *FLG* gene.[2]

ETIOLOGY

④ AD is a complex genetic disease that arises from gene-gene and gene-environment interactions. There are two major groups of genes involved. First, there are the genes encoding for epidermal or other epithelial structural proteins. Second, there are genes encoding for the major elements of the immune system.[5] However, the diagnosis of AD remains clinical, as there is no reliable biomarker to distinguish AD from other inflammatory conditions.[15]

The inheritance pattern is not straightforward. More than one gene is likely involved in the disease. There is an increased risk for a child to have AD if there is a family history of other atopic diseases, such as hay fever or asthma. The risk of AD is two- to threefold higher in children with one atopic parent and three- to fivefold higher if both parents are atopic.[2] Studies of identical twins show that a person whose identical twin has AD is seven times more likely to have AD than someone in the general population.[1] And a person whose fraternal twin has AD is three times more likely to have AD than someone in the general population.[1] Another estimate is 80% concordance in monozygous twins and 20% in heterozygous twins.[10]

Thus, genetic predispositions to developing AD exist. There is a genetic predisposition in patients with atopy to demonstrate T-helper (Th_2) predominance—hence increased Th_2 cell activity.[3] At least 32 susceptibility loci have been identified through gene-mapping studies, but they explain less than 20% of the estimated heritability.[3] The strongest known genetic risk factor for AD is null mutations in filaggrin (FLG).[3] The filaggrin gene (*FLG*) on chromosome 1q21.3 encodes for a key structural protein in epidermal differentiation.[3] FLG mutations also cause the semidominant skin-scaling disorder ichthyosis vulgaris, characterized by abnormal skin dryness and palmer hyperlinearity, which are features often found in AD.[3] More specifically, there are several possible genes on the chromosomes 3q21, 1q21, 16q, 17q25, 20p, and 3p26. Of these chromosomes, 1q21 has the highest linkage region. This region has a family of epithelium-related genes called the epidermal differentiation complex.[5] One of these genes is the *FLG*, on chromosome 1q21.3, which encodes for profilaggrin that degrades to filaggrin proteins.[2] Filaggrin proteins play key roles in epidermal differentiation, including terminal differentiation of the epidermis and formation of the skin barrier (including the stratum corneum).[2,16] Filaggrin breakdown products are natural moisturizers and contribute to epidermal hydration and barrier function.[2] Mutations or deficiency of *FLG* result in an abnormality in permeability barrier function.[16] Patients with AD who carry FLG mutations have more persistent disease, a higher incidence of skin infections with herpes virus (eczema herpeticum) and a greater risk for multiple allergies.[16] However, FLG mutation is neither necessary nor sufficient to cause AD. Up to 60% of carriers will not develop AD, and many patients with AD do not carry an FLG mutation.[3]

Epidermal barrier dysfunction is a prerequisite for the penetration of high-molecular-weight allergens in pollens, house dust mite products, microbes, and food.[5] In mice studies, this barrier abnormality lowers irritability thresholds, and enhanced cutaneous allergen penetration.[16] In humans, two common FLG variants (*R501X* and *2282de14*) with an estimated combined allele frequency of about 6% have been identified in individuals of European descent.[17] Eighteen other less common variants have also been identified in Europeans, with an additional 17 mutations restricted to individuals of Asian descent.[17] Each of these variants leads to nonsense mutations that either prevent or severely diminish the production of filaggrin in the epidermis.[17] Mutations of FLG occur mainly in patients with early onset AD and may be associated with the development of asthma in patients with AD.[5,17] However, FLG mutations are identified in only 30% of European patients with AD, implying that other genetic mutations affecting other epidermal structures may be important (eg, changes in the cornified envelope proteins involucrin and loricrin, or lipid composition).[5]

④ There are other genes encoding for the immune system that may be associated with AD, especially those on chromosome 5q31-33.[5] These genes code for cytokines that regulate IgE synthesis. Cytokines are produced by helper T cells (TH_0, TH_1, TH_2, TH_3).[11] T-helper type 1 (TH_1) cells produce cytokines that suppress immunoglobulin E (IgE) production (eg, interferon-γ and interleukin-12 [IL-12]).[5] T-helper type 2 (TH_2) cells produce cytokines that increase IgE production (eg, IL-5 and IL-13).[5,18] In patients with AD, there is an imbalance between TH_1 and TH_2 immune responses. These patients are genetically predisposed to TH_2 predominance, seen as increased TH_2 cell activity.[2,5,9,18] Increased TH_2 activity causes the release of IL-3, IL-4, IL-5, IL-10, and IL-13, resulting in blood eosinophilia, increased total serum IgE, and increased growth and development of mast cells.[2,5,11,18] This is seen in the initial and acute phase of AD.[9] In addition, these cytokines affect the maturation of B cells and cause a genomic rearrangement in these cells that favors isotype class switching from immunoglobulin M (IgM) to IgE.[5] As discussed below, epidermal Langerhans cells (LCs) and dendritic cells (DCs) with high-affinity IgE receptors uptake allergens and mediate the inflammatory response.[11]

In summary, FLG deficiency alone can provoke a barrier abnormality in the epidermis and predispose to the development of AD by enhancing allergen absorption through the skin.[19] Furthermore, there is complex relationships, including genetic and nongenetic risk factors, that modify an individual's susceptibility to allergic disease.[20] Complex genetic factors contribute to the increased susceptibility to AD (FLG mutations and gene-gene interactions). These, along with environmental factors such as food allergens[21] (gene-environment interactions), result in the pathophysiologic changes and clinical presentations associated with AD.

PATHOPHYSIOLOGY

④ The initial mechanisms that trigger inflammatory changes in the skin in patients with AD are unknown. Neuropeptides, irritation, or pruritus-induced scratching may be causing the release of proinflammatory cytokines from keratinocytes. Alternatively, allergens in the epidermal barrier or in food[21] may cause T-cell mediated but IgE-independent reactions. Allergen-specific IgE is not a prerequisite.[5] Characteristic features in pathophysiology are skin barrier dysfunction and immune deviation toward TH_2 with subsequent increased IgE.[10] The disease is further complicated by microbial colonization with pathologic organisms resulting in increased susceptibility for skin infections.[10]

As discussed above, skin barrier dysfunction plays a critical role in the development of AD,[10,11,16,22] with loss of function mutations in *filaggrin* being a major risk factor.[16,22] Other factors may include a deficiency of skin barrier proteins, increased peptidase activity, lack of certain protease inhibitors, and lipid abnormalities.[22] There must be epidermal barrier dysfunction for high-molecular-weight allergens in pollens, house dust mite particles, microbes, and foods to penetrate the skin barrier. Atopic skin has reduced antimicrobial peptides (AMPs). AMPs are normally produced by keratinocytes, sebocytes, and mast cells, and they form a chemical shield on the surface of the skin. Reduced AMPs result in a diminished antimicrobial barrier, which correlates with increased susceptibility to infections and superinfections seen in these patients.[23]

Upon penetration of the epidermal barrier, allergens are met by DCs. DCs are antigen-presenting cells populating the skin, respiratory tract, and mucosa of the GI tract (ie, at the front line of pathogen entry).[24] DCs then enhance TH_2 polarization, resulting in increased production of IgE. Keratinocytes in the skin of patients with AD also produce high levels of an IL-7–like protein, which again drives DCs to enhance TH_2 polarization. Epidermal DCs in patients with AD bear IgE and express its high-affinity receptor (FcεRI).[25–27] Total serum IgE is often elevated in patients with AD,[1,2] especially during an exacerbation.

However, on initial presentation, patients with early onset AD generally do not have increased total serum IgE levels (ie, there is no detectable IgE-mediated allergic sensitization). IgE-mediated allergic sensitization may occur several weeks or months after the initial AD lesions, although in some children—mostly girls—this sensitization never occurs.[5] Furthermore, elevated total serum IgE is not specific to AD and can be associated even with nonatopic conditions.[2]

Other potential biomarkers discovered include serum CD30, macrophage-derived chemoattractant (MDC), interleukins (IL)-12, -16, -18, and -31, and thymus and activation-regulated chemokine (TARC); however, to date none of them have shown reliable sensitivity nor specificity for clinical use.[2]

Predisposing Factors

4 Several factors can predispose patients to development of AD. These include climate, infection, genetics, environmental aeroallergens, urban versus rural living, breastfeeding and time of weaning, obesity, pollution/tobacco smoke, and food/diet. A Western diet with high amounts of sugar and polyunsaturated fatty acids, a small family size, a high education level in the household, living in urban settings, and living in regions with low exposure to UV radiation and low humidity are all factors that may increase the risk of AD.[3]

Hot and extremely cold climates are both poorly tolerated by patients with AD. Dry weather, common in the winter, causes increased skin dryness. Hot weather causes increased sweating, resulting in pruritus.

Patients with AD are commonly colonized by *Staphylococcus aureus* bacteria. Clinical infections with *S. aureus* frequently cause flare-ups of AD.

As discussed previously, genetics plays a role in AD. Family history of AD is a strong risk factor.

4 Exposure to environmental aeroallergens is another risk factor. Dust mites, pollens, molds, cigarette smoke, and dander from animal hair or skin may worsen the symptoms of AD.[13]

The role of food as antigens in the pathogenesis of AD is still not fully understood.[3,21] Preliminary results (mostly animal studies) indicate that defects in the skin and gut barrier function may facilitate sensitization to food allergens.[21] Small amounts of environmental foods (low-dose exposure from foods on tabletops, hands, dust) may penetrate the skin barrier and be taken up by LCs, leading to TH_2 responses and IgE production.[28] However, early high-dose oral food consumption induces oral tolerance. The timing and balance of cutaneous and oral exposure determines whether a child will have allergy or tolerance.[28] Increased serum IgE antibodies to a particular food is evidence of sensitization to a food and is consistent with—although not proof of—a food allergy.[1,29] Eczema may frequently be a manifestation of food allergy,[28] and patients with AD have a higher prevalence of food allergy than those in the general population.[1] Conversely, there is a belief that food allergy may be caused by AD, and in most patients with coexisting AD and food allergy, AD precedes the food allergy. (The assumption is that AD is a causal risk factor for asthma and systemic allergen sensitization in the context of FLG mutations.[16]) Regardless, the two conditions coexist, and the likelihood of an infant or child with AD also having food allergy or other allergies must be kept in mind.[29]

There is a known epidermal barrier dysfunction in AD, allowing for increased low-level skin permeability to allergenic foods. Certain foods may trigger acute reactions including urticaria and anaphylaxis. The most commonly reported allergenic foods are hen's eggs, cow's milk, peanuts, wheat, soy, tree nuts, shellfish, and fish.[1,30] Individual food allergies, such as peanut allergy, have increased in prevalence in the past decade[28,29]; new food allergies may also be increasing in prevalence, particularly kiwi allergy[28,31] and sesame seed allergy.[28,32] Allergies to seafood, peanuts, and tree nuts are more likely to persist into adulthood, while allergies to cow's milk, hen's eggs, wheat, and soy generally resolve by late-childhood.[21] Consistent with the oral tolerance concept, early results from recent studies using sublingual and oral immunotherapy to specific food allergens (eg, cow's milk or peanut) indicate that it may be possible to induce oral tolerance, and that it may be possible to desensitize children to some allergenic foods.[33] Nine to 12 months of immunotherapy were needed to observe the beneficial effect and "the present evidence does not warrant routine recommendation" by the AAD.[34] Injectable allergen-specific immunotherapy is also being studied.[34] National Institute of Allergy and Infectious Diseases (NIAID) suggests limited food allergy testing (ie, cow's milk, eggs, wheat, soy, peanut) if a child <5 years old has moderate-to-severe AD and persistent disease despite optimal therapy.[29,34] For more information about management of food allergies the reader is directed to the 2010 NIAID-sponsored expert panel's report, available at www.niaid.nih.gov.[29]

CLINICAL PRESENTATION

Diagnosis of AD is generally based on clinical presentation (Table 119-2).[1] There is no objective diagnostic test or reliable biomarker for the clinical confirmation of AD.[1–3] On occasion, skin biopsy specimens or other tests (eg, total and/or allergen-specific serum IgE, potassium hydroxide preparation, patch testing, and/or genetic testing) may be used to rule out other or associated skin conditions.[2] *Filaggrin* gene mutations may be associated with persistent and more severe AD as well as early onset cases.[22]

TABLE 119-2

Skin Features Associated with Atopic Dermatitis

- **Atopic pleat (Dennie–Morgan fold):** An extra fold of skin that develops under the eye.
- **Headlight sign:** Sparing of the skin on top of the nose.
- **Herthoge's sign:** Thinning or absence of the lateral portions of the eyebrows.
- **Cheilitis:** Inflammation of the skin on and around the lips.
- **Hyperlinear palms:** Increased number of skin creases on the palms.
- **Hyperpigmented eyelids:** Eyelids that have become darker in color from inflammation or hay fever.
- **Ichthyosis:** Dry, rectangular scales on the skin.
- **Keratosis pilaris:** Small, rough bumps, generally on the face, upper arms, and thighs.
- **Lichenification:** Thick, leathery skin resulting from constant scratching and rubbing.
- **Papules:** Small raised bumps that may open when scratched and become crusty and infected.
- **Urticaria:** Hives (red, raised bumps) that may occur after exposure to an allergen, at the beginning of flares, or after exercise or a hot bath.

Atopic dermatitis follows a relapsing course.[34,35] Studies reviewing the natural course of the disease usually describe the disease pattern as persistent, intermittent, or in remission.[8] A 2004 study found that 43% were in complete remission after the age of 2 years, with 19% having persistent disease and 38% an intermittent pattern.[8]

⑤ The clinical presentation of AD differs depending on the age of the patient. In infancy, the earliest onset of AD usually occurs between 3 and 6 months of age, with 60% of patients developing symptoms within the first year of life, and 85% to 90% having developed symptoms before the age of 5 years.[1,2] The initial presentation in infancy is an erythematous, papular skin eruption that may first appear on the cheeks and chin as a patchy facial eruption which may progress to red, scaling, oozing skin.[1] The eruption shows a centrifugal distribution affecting the malar region of the cheeks, forehead, scalp, chin, and behind the ears while sparing the central areas (ie, the nose and paranasal creases). Sparing of the skin on top of the nose is a characteristic feature (known as the "headlight sign"), and there is thinning or absence of the lateral portions of the eyebrows (known as the Herthoge's sign).[3] Lesions occur in the flexor surfaces, such as antecubital and popliteal fossae. Over the next few weeks and as the infant becomes more mobile and begins crawling, the lesions spread to the extensors of the lower legs, and eventually the entire body may be involved, with sparing of the groin, axillary region, and the nose.[1,2,35] These lesions are associated with uncontrollable itchiness, and the infant will become irritable and may try to rub his or her face to relieve the itch. Scratching may occur quite early, and infants with AD may scratch themselves continuously, even during sleep.[2] Sleep disruption occurs in up to 60% of children with AD, increasing to 80% or more during exacerbations.[2] Excessive rubbing or scratching may result in excoriation and predispose the patient to secondary infections.

In childhood, the skin is often dry, flaky, rough, cracked, and may bleed because of scratching. With repeated scratching and rubbing, the skin becomes lichenified. Lichenification, usually localized to the flexural folds of the extremities, is characteristic of childhood AD in older children and in adults.[35] Lichenification signifies repeated rubbing of the skin and is seen mostly over the folds, bony protuberances, and forehead.[35] Excoriations and crusting are also commonly seen, along with secondary infections. Sometimes increased folds are seen underneath the eyes (so-called Dennie–Morgan folds).[35] Lesions are still most commonly seen in the flexor surfaces of the body, particularly the flexural creases of the antecubital and popliteal fossae.[35]

Sleep disturbances also occur. One study reported that there are both brief and longer awakenings associated with scratching episodes that affect sleep efficiency in school-age children with AD.[36]

In adulthood, lesions are more diffuse with underlying erythema. The face is commonly involved and may be dry and scaly. Lichenification may again be seen. A brown macular ring around the neck, representing a localized deposit of amyloid, is typical but not always present.[35]

In people of color, skin lesions may present in a different manner, often with a perifollicular distribution.

Although no objective diagnostic test confirms the presence of AD,[1,2] some signs, symptoms, and other factors are commonly used in its diagnosis. These include pruritus, early age of onset, eczematous skin lesions that vary with age, chronic and relapsing courses, dry and flaky skin, IgE reactivity, family or personal history of asthma or hay fever, or other atopic diseases (Tables 119-3 and 119-4).[2,35] Allergy skin testing has little utility in AD, although negative results may help rule out certain substances as triggers; however, positive results may be unrelated to disease activity, and false positives are common.[1]

TABLE 119-3

Clinical Features in the Diagnosis of Atopic Dermatitis

Essential Features (Must Be Present):

- Pruritus
- Eczema (acute, subacute, chronic)
    - Typical morphology and age-specific patterns
        - Facial, neck, external involvement (infants, children)
        - Flexural lesions (any age group)
        - Sparing of groin and axillary regions
    - Chronic or relapsing history

Important Features (Seen in Most Cases, Supports the Diagnosis of AD):

- Early age of onset
- Atopy
    - Personal/family history
    - IgE reactivity
- Xerosis

Data from Reference 2.

TABLE 119-4

Major and Minor Signs and Symptoms of Atopic Dermatitis

Major Indicators

- Pruritus (intense itching)
- Characteristic rash in locations typical of the disease
- Chronic or repeatedly occurring symptoms
- Personal or family history of atopic disorders (eczema, hay fever, asthma)

Selected Minor Indicators

- Early age of onset
- Dry skin that may also have patchy scales or rough bumps
- Increased serum IgE
- Numerous skin creases on the palms
- Hand or foot involvement
- Inflammation around the lips
- Nipple eczema
- Susceptibility to skin infection
- Positive allergy skin tests

Data from Reference 1.

① Pruritus is a quintessential feature of AD, and a diagnosis cannot be made if there is no history of itching.[1–4,35] Scratching and rubbing itchy atopic skin further irritates the skin, increases inflammation, and exacerbates itchiness.[3] Atopic skin can itch during sleep. This nighttime itching is a problem for many infants and children with the disease, since there is no conscious control of scratching during sleep.[1,2] Pruritus is the symptom that most affects the health-related quality of life for most patients with AD. In studies, more than 50% of patients rated their pruritus as bothersome or extremely bothersome and reported that they often or always experienced intolerable symptoms.[35]

Pruritus can be triggered by a variety of factors. The most common triggers of itch have been reported as heat and perspiration (96%), wool (91%), emotional stress (81%), certain (usually vasodilatory) foods (49%), alcohol (44%), upper respiratory infections (36%), and house dust mites (>35%).[35,36]

Once pruritus occurs, the surrounding normally nonpruritic skin area (whether inflamed or noninflamed) may be sensitive and react to light stimuli and begin itching (a process known as *allokinesis*). Allokinesis is typical of AD.[35,36] As a result of allokinesis, patients with AD may experience pruritic attacks when their skin is touched accidentally by mechanical factors such as clothing, especially wool products.[36]

Elevated serum IgE may be seen, consistent with the genetically predetermined dominance of TH_2 cytokines causing increased IgE. In addition, increased serum IgE antibodies to a particular food, consistent with a food allergy, is common in patients with AD. Serum-based tests for allergen-specific IgE (formerly a radioallergosorbent test referred to as RAST) are used to screen for allergy to a specific substance or substances.[34] (Most labs use large autoanalyzers that rely on fluorescent or chemiluminesent labels rather than radiolabels to identify reactions, so RAST does not describe the technique used). In some cases, allergen-specific IgE tests may be used to monitor immunotherapy or to see if a child has outgrown a specific allergy. The negative predictive value is high (>95%) but the specificity and positive predictive value are low (40%-60%).[34] Negative results help to rule out a food allergy, whereas positive (elevated) allergen-specific IgE test results only signify sensitization and require clinical correlation and confirmation.[34] The level of IgE may not correlate with the severity of an allergic reaction or with the severity of AD.

With respect to IgE reactivity, several candidate genes that encode cytokines involved in the regulation of IgE synthesis have been identified, notably on chromosome 5q31-33.[2] Increased Th_2 activity leads to release of IL-3, IL-4, IL-5, IL-10, and IL-13, which causes eosinophilia, increases IgE, and increases the growth and development of mast cells.[35] In addition to eosinophils and mast cells, basophils and newly identified innate immune cells called group 2 innate lymphoid cells (ILC2s) have been shown to underlie the pathogenesis of AD.[35] The above cytokines also affect B-cell maturation, causing a genomic rearrangement that favors isotype class switching from IgM to IgE.[2] Th_{17} cells have been found to be elevated, with its role not yet clearly defined.[35]

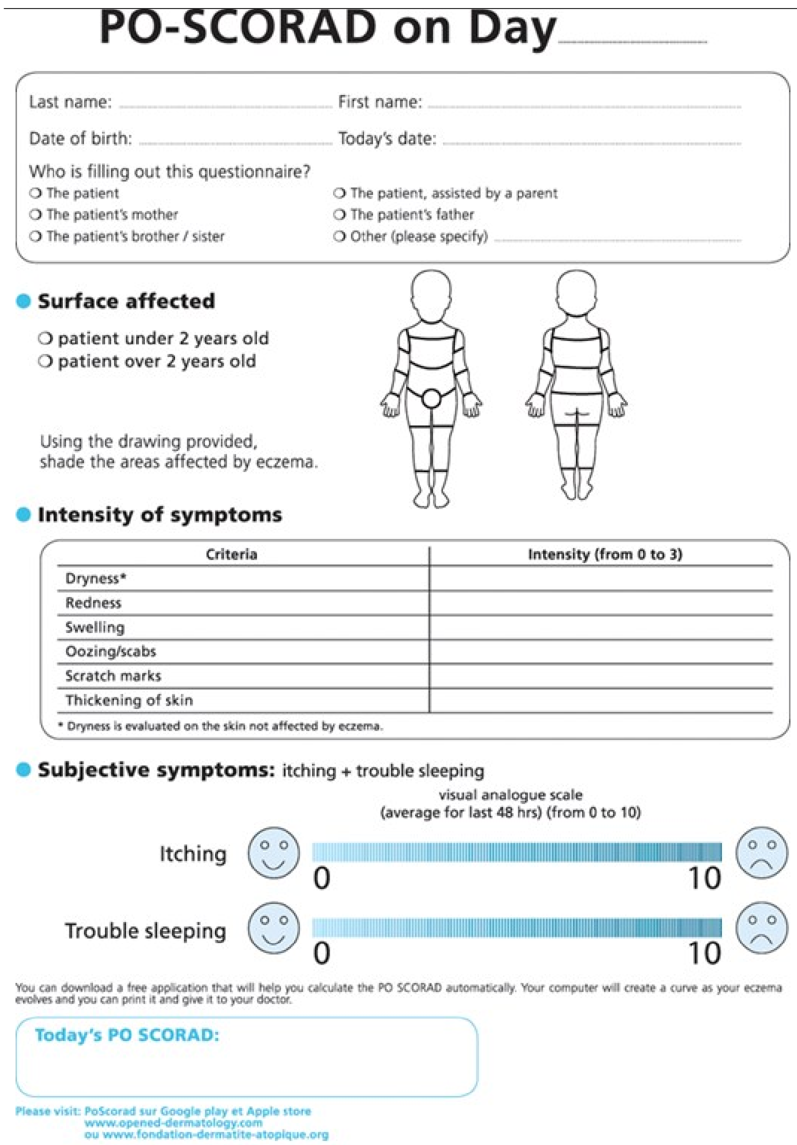
A clinically useful set of criteria for the diagnosis of AD is as follows: atopy, pruritus, eczema, and altered vascular reactivity.

Disease Severity

⑥ Disease severity can be classified as mild, moderate, or severe. Assessing the severity of AD includes subjective symptoms and objective signs—in particular, the subjective evaluations relating to pruritus and sleep disturbance are particularly important. Composite scores assessing both signs and symptoms must be used to assess overall disease severity.[36] SCORAD (Scoring of Atopic Dermatitis) is a composite score developed by the European Task Force of Atopic Dermatitis (ETFAD), where a SCORAD score >50 defines severe AD, and one <25 considered mild AD.[36] There is also a Patient-Oriented SCORAD (PO-SCORAD) which is also useful since it can be administered independent of the physician; and the PO-SCORAD correlates well with SCORAD.[36] In addition, there is an objective assessment tool for visible lesions called EASI (Eczema Area and Severity Score) which is often used together with a subjective symptom assessment tool called POEM (Patient-Oriented Eczema Measures); this pair of tests is especially useful in the clinical trial setting.[36] Both SCORAD and PO-SCORAD are available as apps from the Eczema Foundation at https://www.fondation-dermatite-atopique.org/en/healthcare-professionals-space (Fig. 119-1).

FIGURE 119-1

Example of use of SCORAD tool for atopic dermatitis disease severity assessment. A composite score of 40.8 would be consistent with moderate disease. (*SCORAD and POSCORAD copyright © Pr JF Stalder, Eczema Foundation, 2020. Reprinted with permission.*)



PO-SCORAD on Day ....

Last name: .... First name: ....
Date of birth: .... Today's date: ....

Who is filling out this questionnaire?

○ The patient
○ The patient's mother
○ The patient's brother / sister
○ The patient, assisted by a parent
○ The patient's father
○ Other (please specify) ....

Surface affected

○ patient under 2 years old
○ patient over 2 years old

Using the drawing provided,
shade the areas affected by eczema.

Intensity of symptoms

Criteria	Intensity (from 0 to 3)
Dryness*	
Redness	
Swelling	
Oozing/scabs	
Scratch marks	
Thickening of skin	

* Dryness is evaluated on the skin not affected by eczema.

Subjective symptoms: itching + trouble sleeping

visual analogue scale
(average for last 48 hrs) (from 0 to 10)

Itching 0 10
Trouble sleeping 0 10

You can download a free application that will help you calculate the PO SCORAD automatically. Your computer will create a curve as your eczema evolves and you can print it and give it to your doctor.

Complications

⑦ Patients with AD are prone to skin infections. Atopic skin is drier and the stratum corneum has weakened protective abilities; combined with the abnormal skin barrier function and immune defense, there is an increased risk of secondary bacterial skin infections with staphylococci or streptococci, and viral infections such as herpes simplex or even fungal infections.[1,2] Constant scratching to relieve pruritus may cause excoriations, further compromising the integrity of the skin barrier. *S. aureus* is a common cause of secondary bacterial infections in AD.[3,10] Binding of *S. aureus* is enhanced by skin inflammation as seen in AD. Many patients with AD are colonized with *S. aureus* and may have exacerbations after skin infections of this organism.[10] Secondary bacterial infections may present as yellowish crusty lesions and should be promptly treated. Oral (systemic) antibiotics are generally more effective than topical treatment.[1]

Patients with AD are also more prone to disseminated infections with herpes simplex or vaccinia virus. Severe viral infections such as eczema herpeticum or eczema vaccinatum might be linked to the severity of atopy. Eczema herpeticum is a severe widespread skin infection with herpes simplex virus (HSV) that occurs in up to 3% of patients, in particular those with severe disease.[3] *Molluscum contagiosum* virus infection may be seen in children and adolescents with AD.[3] Smallpox vaccination is contraindicated in patients with AD.

TREATMENT

Desired Outcomes

In treating patients with AD, clinicians generally have the following clinical goals in mind:

1. Provide symptomatic relief—control the itching.
2. Control the AD.
3. Identify and, when possible, eliminate triggers and environmental aeroallergens.
4. Identify and minimize predisposing factors for exacerbations including any stressors.
5. Prevent future exacerbations.
6. Provide any social and psychological support needed for the patient, family, and caregivers.
7. Minimize or prevent adverse events from medications and other treatment modalities.
8. Treat to cure any secondary skin infections, if present.

Successful management of AD should include not only clearance of skin lesions, which may take days to weeks depending on the severity of disease—and this determines the type of treatment regimen—but also controls of the itch, minimizing or eliminating triggers, monitoring the patient to minimize or prevent adverse events from medications or other treatment modalities, and providing adequate social and psychological support for the patient, family, and caregivers.

The ultimate goal is to provide enough control of this chronic disease so that future exacerbations are prevented, thus ensuring that the patient's quality of life is minimally affected by AD. Because the course of the disease evolves over time, management strategies may change. Mild disease can be managed by reactive therapy, moderate-to-severe disease will require proactive therapy to maintain disease control.[36]

⑧ Both nonpharmacologic and pharmacologic therapies are important in managing the signs and symptoms of AD. Nonpharmacologic strategies include identifying and minimizing or eliminating preventable risk factors, such as known triggers and allergens, as well as appropriate skin care.[30,36]

Treatment guidelines and protocols for AD are available. These are listed in Table 119-5. At the time this chapter was prepared for publication, the American Academy of Dermatology (AAD) was updating its 2014 guidelines in a series of publications.[37] The reader is encouraged to access the online version of this chapter for updates.

Nonpharmacologic Therapy

⑧ ⑨ Nonpharmacologic approaches to the treatment of infants and children with AD include the following[30,36,38]:

1. Apply moisturizers frequently throughout the day. Moisturizers are a standard of care for AD and there is strong evidence that their use can reduce disease severity and the need for pharmacologic intervention.[30,36,38] Long-term moisturizer therapy improves AD associated xerosis.[36] Even stand-

alone use of moisturizers for 1 week improves mild-to-moderate AD flares.[39] Daily use of moisturizers from birth may reduce the development of AD in a high-risk population.[36,40]

2. Give lukewarm baths. There is insufficient evidence for patients with AD to recommend the addition of oils, emollients, or most other additives to bath water, or the use of acidic spring water.[38]
3. Apply moisturizer immediately after bathing. There is no standard for the frequency or duration of bathing appropriate for those with AD.[38]
4. Use nonsoap cleansers (which are neutral to low pH, hypoallergenic, fragrance free). Limited use.[38]
5. Use wet-wrap therapy (with or without TCS) during flare-ups for patients with moderate-to-severe AD. "Wet wrap" is applying damp tubular elasticized bandages and occlusive dressing to the limbs—this promotes skin hydration and absorption of emollients and TCS,[11] reducing disease severity and water loss.[11,38]
6. Keep child's fingernails filed short.
7. Select clothing made of soft cotton fabrics.
8. Consider using sedating antihistamines to reduce scratching at night.
9. Keep the child cool; avoid situations in which overheating occurs.
10. Learn to recognize skin infections and seek treatment promptly.
11. Attempt to distract the child with activities to keep him or her from scratching.
12. Identify and remove irritants and allergens.

Hydration is crucial, and adequate skin hydration is a fundamental part of managing AD.[30,36,38] Transepidermal water loss is greater in atopic skin than in normal skin. Thus, any measures to improve skin moisturization, such as liberal use of moisturizers, would be beneficial. Moisturizers are a standard of care and may be steroid sparing.[10,36,38] They are useful for both prevention and maintenance therapy.[10,38,41,42] They can be categorized based on their specific effects on the skin:

1. *Occlusives*: These agents provide an oily layer on the skin surface to slow transepidermal water loss, increasing the moisture content of the stratum corneum. These are the best moisturizers for patients with AD.
2. *Humectants*: In the stratum corneum, these agents increase the water-holding capacity. However, they are not useful in patients with AD because they have a stinging effect on open skin. Humectants act by drawing moisture from their surroundings to attract water to the skin surface. In humid environments, this works well; however, in dry and low humidity environments, humectants can draw water from deeper parts of the skin, thus further drying out the skin. Thus, they are not recommended for patients with AD.
3. *Emollients*: These agents smooth out the surface of the skin by filling the spaces with droplets of oil. As moisturizers, these are less effective than occlusives, but they can be useful in patients with AD.

However, note that the term "emollients" is often more broadly used to mean *all* nonmedicated moisturizers, including occlusives.[36] Nonmedicated "emollients" may also include active ingredients, softening the delineation of emollients from topical drugs.[36] The 2018 European consensus guideline defines *emollients* as "topical formulations with vehicle-type substances lacking active ingredients" and *emollients plus* as "topical formulations with vehicle-type substances and additional active, nonmedicated substances."[36] Usual ingredients in emollients can include mineral oil, petrolatum, and urea.[36] Emollient-plus products may contain active ingredients such as saponins, flavonoids, riboflavins from protein-free oat plantlet extracts, or bacterial lysates from *Aquaphilus dolomiae* or *Vitreoscilla filiformis*.[36,43] These lysates both improve AD and positively influence the skin microbiome.[36,44] A cream based on *Aquaphilus dolomiae* extracts alleviates nonhistaminergic pruritus.[45] Ceramide-containing OTC moisturizers and prescription emollient devices (PEDs) with distinct ratios of lipids mimic endogenous compositions. However, to date these have not shown superiority in AD.[38]

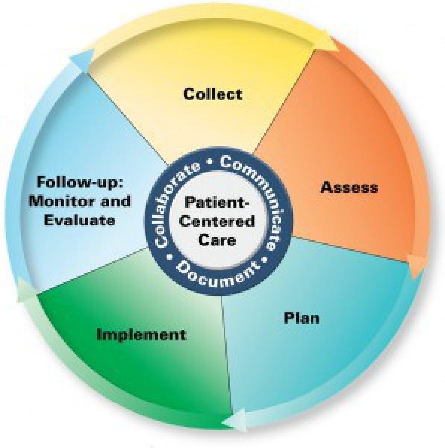
The humidity in the home should be kept at or above 50% and the room temperature kept on the cool side.[46]

Appropriate skin care is crucial in preventing flare-ups.[1] A daily skin care routine should include the following[46]:

1. Using scent-free moisturizers liberally as needed each day. Large quantities can be used.
2. Bathing in lukewarm water (never hot) for 5 to 10 minutes, once or twice daily.[30,36,38]. Adding a capful of emulsifying oil[10] may help the body retain moisture; baths are better than showers. Bathing daily for 10 to 20 minutes may be desirable as long as a thick moisturizer is applied afterward. A 20-minute soak followed by immediate application of topical anti-inflammatory agents (eg, TCS) without towel drying is known as the "soak and smear" technique and is useful when the topical anti-inflammatory agent alone is inadequate.[38] Bathing twice daily during disease flares may also be a useful method for enhancing skin penetration of topical therapies and for debridement of crusting and staphylococcal colonization. The skin should be lightly towel dried (pat to dry, avoid rubbing or brisk drying).[1,46]
3. Scent-free moisturizer should then be applied while the skin is still moist or slightly damp (eg, within 3 minutes of towel drying).[46] Some fragrance-free moisturizers include Aveeno Baby Soothing Relief Moisture Cream, CeraVe lotion, Cetaphil, Neutrogena Hand Cream, and Vanicream products. Lotions may be used on the scalp and other hairy areas and for mild dryness on the face, trunk, and limbs; creams are more occlusive than lotions; ointments are the most occlusive and can be used for drier, thicker, or more scaly areas.[46]
4. Using nonsoap skin cleansers[1] may cause less skin irritation. Lipid- and fragrance-free skin cleansers may be particularly advantageous (eg, CeraVe facial cleansers [Foaming, Hydrating], CeraVe Eczema Body Wash, Cetaphil Gentle Skin Cleanser, Free and Clear Liquid Cleanser, Spectro Derm Cleanser, and Trisan Antibacterial Skin Cleanser). Aquanil, Dove, Neutrogena, and pHisoderm sensitive skin products have also been recommended as low-irritant products, and some are lipid free.
5. Avoiding alcohol-containing topical products including lotions, swabs, and wipes, as they may be drying.
6. Clothing should be double-rinsed. Mild detergents should be used to wash clothing, with no bleach or fabric softener.

PATIENT CARE PROCESS

Patient Care Process for Atopic Dermatitis



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, pregnancy status)
- Patient medical history (personal and family)

- Patient/caregiver description of history of atopic dermatitis, subjective complaints of itch and other symptoms
- Signs associated with severity of itch (eg, excoriations, sleep disturbances)
- Signs associated with severity of atopic dermatitis (eg, areas of involvement)
- Signs of secondary skin infections
- Signs of caregiver stress or distress

Assess

- Severity of atopic dermatitis—classify into mild, moderate, or severe disease (eg, using SCORAD)
- Severity of itch
- Ability/willingness to pay for medical treatment options
- Emotional/psychological concerns (for patient and caregiver, if any)

Plan*

- Determine an appropriate treatment approach, that is, proactive versus reactive therapy
- Recommend the most appropriate therapies (nonpharmacologic and pharmacologic) for atopic dermatitis and itch
- Recommend the most appropriate treatment (treat to cure) and ongoing preventative strategies for secondary skin infection, if present
- Recommend management strategies for caregiver stress or distress, if needed

Implement

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Provide information about prevention of future flare-ups

Follow-up: Monitor and Evaluate

- Contact patient/caregiver in 1 to 2 weeks to follow-up about the efficacy of recommended therapies and any issues with the treatment regimen
- Ensure that appropriate monitoring parameters for efficacy and potential adverse effects have been put in place (eg, follow-up lab tests as needed)
- Reinforce preventive measures including continuation of proactive therapy, if implemented
- Ensure that patient/caregiver has been connected to other health resources as needed for follow-up (eg, a dermatologist, psychologist)

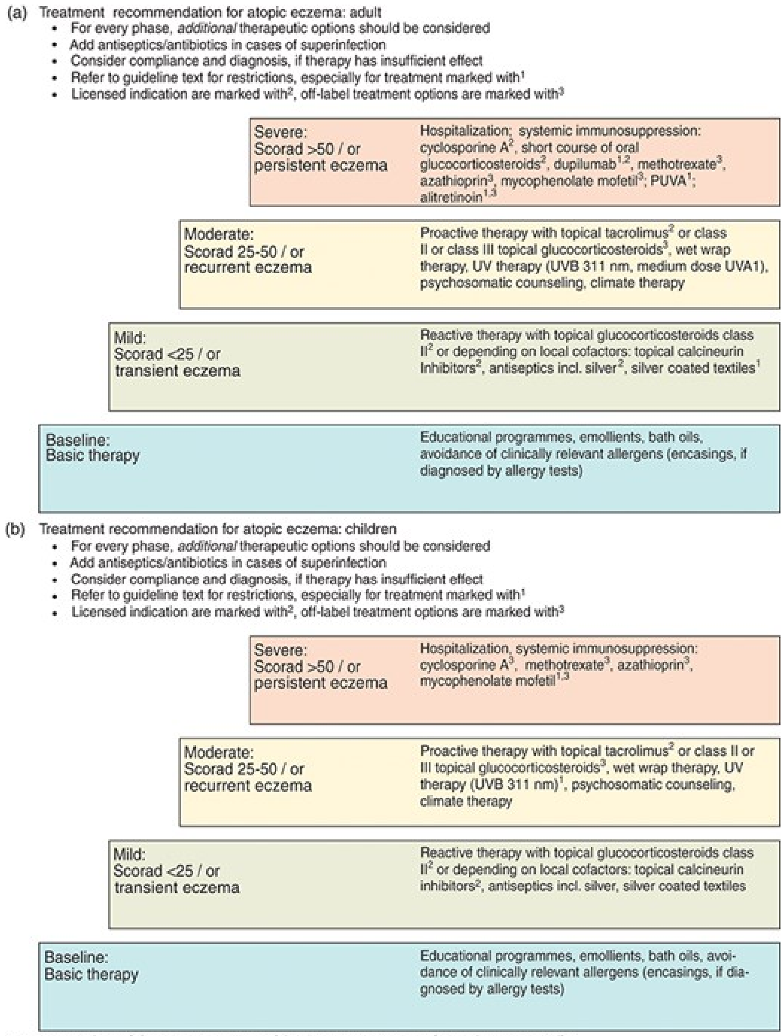
Collaborate with patient, caregivers, and other healthcare professionals.

Pharmacologic Therapy

Current treatment recommendations are based on disease severity, with reactive therapy appropriate for mild disease, and proactive therapy for moderate or severe AD—severe disease most appropriately managed initially with systemic therapy in a hospital setting (see Fig. 119-2).

FIGURE 119-2

Stepwise treatment for atopic dermatitis in adults and children. (*Reprinted, with permission, from Wollenberg A, Barbarot S, Bieber T, et al. Consensus-based European guidelines for treatment of atopic eczema (atopic dermatitis) in adults and children: Part I & part II. J Eur Acad Dermatol Venereol. 2018;32(5):657–682.*)



(a) Treatment recommendation for atopic eczema: adult

- For every phase, *additional* therapeutic options should be considered
- Add antiseptics/antibiotics in cases of superinfection
- Consider compliance and diagnosis, if therapy has insufficient effect
- Refer to guideline text for restrictions, especially for treatment marked with[1]
- Licensed indication are marked with[2], off-label treatment options are marked with[3]

Severe: Scorad >50 / or persistent eczema	Hospitalization; systemic immunosuppression: cyclosporine A[2], short course of oral glucocorticosteroids[2], dupilumab[1,2], methotrexate[3], azathioprin[3], mycophenolate mofetil[3]; PUVA[1]; alitretinoin[1,3]
Moderate: Scorad 25-50 / or recurrent eczema	Proactive therapy with topical tacrolimus[2] or class II or class III topical glucocorticosteroids[3], wet wrap therapy, UV therapy (UVB 311 nm, medium dose UVA1), psychosomatic counseling, climate therapy
Mild: Scorad <25 / or transient eczema	Reactive therapy with topical glucocorticosteroids class II[2] or depending on local cofactors: topical calcineurin Inhibitors[2], antiseptics incl. silver[2], silver coated textiles[1]
Baseline: Basic therapy	Educational programmes, emollients, bath oils, avoidance of clinically relevant allergens (encasings, if diagnosed by allergy tests)

(b) Treatment recommendation for atopic eczema: children

- For every phase, *additional* therapeutic options should be considered
- Add antiseptics/antibiotics in cases of superinfection
- Consider compliance and diagnosis, if therapy has insufficient effect
- Refer to guideline text for restrictions, especially for treatment marked with[1]
- Licensed indication are marked with[2], off-label treatment options are marked with[3]

Severe: Scorad >50 / or persistent eczema	Hospitalization, systemic immunosuppression: cyclosporine A[3], methotrexate[3], azathioprin[3], mycophenolate mofetil[1,3]
Moderate: Scorad 25-50 / or recurrent eczema	Proactive therapy with topical tacrolimus[2] or class II or III topical glucocorticosteroids[3], wet wrap therapy, UV therapy (UVB 311 nm)[1], psychosomatic counseling, climate therapy
Mild: Scorad <25 / or transient eczema	Reactive therapy with topical glucocorticosteroids class II[2] or depending on local cofactors: topical calcineurin inhibitors[2], antiseptics incl. silver, silver coated textiles
Baseline: Basic therapy	Educational programmes, emollients, bath oils, avoidance of clinically relevant allergens (encasings, if diagnosed by allergy tests)

Reactive therapy is the traditional treatment modality where anti-inflammatory agents are used only during disease flares with moisturizers used alone between flare-ups. Proactive therapy includes a predefined, long-term, anti-inflammatory treatment applied intermittently (usually twice weekly) together with moisturizers and a predefined appointment schedule for clinical examinations which begins *after* all lesions have been successfully treated. The duration of proactive therapy is usually adapted to disease severity and persistence.[36]

Topical Corticosteroids

⑩ *Topical corticosteroids* (TCS) are the standard of care to which other treatments are compared.[10,11,30,36,38,42] They remain the drug treatment of choice for AD. However, despite their extensive use, supporting data are limited regarding optimal corticosteroid concentrations, duration and frequency of therapy, and quantity of application.[10,38] The use of long-term intermittent application of TCS was beneficial and safe in two randomized controlled trials (RCTs); however, independent studies of other formulations are needed.

To maximize the anti-inflammatory benefit and minimize adverse effects, the choice of TCS should be matched with the severity and site of disease. Low-potency TCS, such as hydrocortisone 1%, are suitable for the face, and medium-potency TCS, such as betamethasone valerate 0.1%, may be used for the body. For longer-duration maintenance therapy, low-potency TCS are recommended.[38] Mid-strength and high-potency TCS should be used for short-term management of exacerbations.[38] There is no established optimum regimen for controlling flare-ups—starting with a short burst of high-potency TCS to rapidly control active disease followed by a rapid taper in potency is equally acceptable as using the lowest-potency agent thought to be needed then adjusting upward in potency if treatment fails.[38] Although twice-daily application is the usual clinical practice, there is some evidence of efficacy with once-daily use of some potent TCS.[38] Daily TCS applications are recommended until the inflammatory lesions are significantly improved—which may take up to several weeks at a time. Once control is achieved, either (a) stop the TCS and use moisturizers alone until the next flare-up, or (b) apply a TCS once or twice weekly to areas of the patient's body where frequent/repeated flare-ups occur—this method has reduced rates of relapse for those patients who experience frequent flare-ups at the same body sites[38] and should be used as proactive therapy in patients with moderate-to-severe AD.[36] There are different potencies for corticosteroids which should be used to guide therapy. (For a corticosteroid potency comparison chart, see Table 118–2 in Chapter 118, or visit the National Psoriasis Foundation Website at http://www.psoriasis.org/netcommunity/sublearn03_mild_potency.) Children should be treated with less-potent corticosteroids than adults.[36] Ultrahigh- and high-potency TCS, such as betamethasone dipropionate 0.05% or clobetasone propionate 0.05%, are typically reserved for short-term treatment of lichenified areas in adults.[41] After the lesions have cleared or significantly improved, a lower-potency agent (the least potent TCS that is effective)[38] should be used for maintenance when appropriate.[41] Potent fluorinated TCS should be avoided not only on the face, but also the genitalia and the intertriginous areas, and in young infants.[36]

It is also important to remember that altering the local environment through hydration and/or occlusion (eg, wet-wrap therapy)[11] as well as changing the vehicle[47] may alter the absorption and effectiveness of the TCS.[10] Some vehicles are better suited for certain body areas,[47] such as a lotion for the scalp and hairy areas. Foams may be more cosmetically pleasing to some patients, as they easily disappear into the skin. The surface area of the skin involved and the skin thickness also play a role. In addition, tachyphylaxis is a clinical concern, but there is little experimental documentation.

TCS are efficacious for the itch in addition to improving lesions, and itch is the key symptom for evaluation of response to treatment.[36] Tapering should not be initiated before the itch has largely improved.[36] Dose tapering has been suggested to avoid withdrawal rebound—with various tapering strategies such as to a less potent TCS or by reducing the frequency of application to intermittent treatment (eg, twice weekly).[36] Dose tapering also minimizes side effects.

Adverse effects of TCS may be systemic in nature, and they are directly related to the steroid potency, duration of use, and other factors as discussed above. Local adverse effects include striae distendae (stretch marks) and skin atrophy, perioral dermatitis, acne, rosacea, telangiectasias (rubeosis steroidica), purpura, focal hypertrichosis, a "dirty neck" (cutis punctata linearis colli), spontaneous scars (pseudocicatrices stellaires), and allergic contact dermatitis (often related to the vehicle but may be due to the corticosteroid).[36,38,48] Inappropriate, long-term use of potent TCS on the face can cause a facial rosacea-like disease with persistent erythema, burning and stinging sometimes called the "red face syndrome" or "corticosteroid addiction syndrome."[36] In infants, inappropriate use of high-potency TCS can cause granuloma gluteal infantum or iatrogenic Cushing's disease.[36] The potential for systemic adverse effects is related to the potency of the TCS, the site of application, the occlusiveness of the preparation, the percentage of body surface area covered, and the duration of use. Potential systemic side effects include hypothalamic-pituitary-adrenal (HPA) axis suppression, infections, hyperglycemia, cataracts, glaucoma, and growth retardation (in children).[1,36,38,46,48] However, growth retardation may also be related to the chronicity of the illness rather than to TCS use or dietary factors. Although less likely, systemic adverse effects can occur with low-potency TCS. For example, a phase II study of a mild-potency corticosteroid (desonide 0.05% foam) in children and adolescents 3 months to 17 years showed that 4% (3 out of 75) of patients experienced mild reversible HPA-axis suppression after a 4-week treatment period.[49]

When TCS therapy has failed for efficacy or safety reasons, numerous agents and interventions can be used as alternative or add-on therapy in patients with AD. Some of these interventions are steroid sparing.

Topical Calcineurin Inhibitors

⑪ Topical immunomodulators, such as the topical calcineurin inhibitors (TCIs): tacrolimus ointment (Protopic) and pimecrolimus cream (Elidel), have been shown to reduce the extent, severity, and symptoms of AD in adults and children.[10,36,38,41,42] TCIs inhibit the activation of key cells involved in AD, including T cells and mast cells, blocking the production of proinflammatory cytokines and mediators.[38] Tacrolimus also decreases the number and costimulatory ability of epidermal DCs.[38] Pimecrolimus has more favorable lipophilic characteristics and, in animal studies, appears to preferentially distribute to the skin as opposed to the systemic circulation.[50] Both tacrolimus ointment and pimecrolimus cream are approved for AD in adults and children older than 2 years.[10,36,38,41,42] Although clinical trials conducted in younger infants (eg, 2-23 months old) showed significant efficacy without appreciable adverse effects, use in children younger than 2 years is not Food and Drug Administration (FDA) approved.[51] Tacrolimus 0.03% ointment is approved for moderate-to-severe AD for children aged 2 years and older, with the 0.1% ointment limited to ages 16 years and older; pimecrolimus 1% cream is approved for mild-to-moderate AD for ages 2 years and older.[51] There is limited data comparing TCS with tacrolimus or pimecrolimus. However, it is known that simultaneous combination of TCS with TCI at the same site does not seem to provide greater benefit.[36] Using a TCI at sensitive skin sites such as face and skin folds while using TCS at other sites may be a useful strategy. Unlike TCS, long-term use of TCI does not cause skin atrophy[38]; however, an initial acute site reaction is fairly common.[36]

Proactive therapy (intermittent) using TCI is cost-effective for patients with moderate and severe AD.[36,52,53] However, cost-effectiveness of first-line treatment with TCI has not yet been conclusively demonstrated.[36]

The FDA has a black-box warning for both tacrolimus ointment and pimecrolimus cream about their potential cancer risk, but no causal relationship has been proven between use of a TCI and the development of lymphoma or nonmelanoma skin cancer in humans.[44] However, there is a theoretical potential of local skin carcinogenesis as discussed below. Thus, both tacrolimus and pimecrolimus are recommended for use as second-line treatments for short-term and noncontinuous chronic use in AD,[10,36,38,41,42] when the continued use of TCS is ineffective or inadvisable.[36,38] They may be appropriate in patients with corticosteroid-related adverse effects, patients with large body-surface areas of disease, patients unresponsive to TCS, or other reasons where treatment with TCS is inadvisable. Children and adults with a weakened or compromised immune system should not be treated with these agents.[38] Unlike TCS, TCI can be used on all body locations for prolonged periods,[36] although episodic use is recommended. They may be used as twice-weekly long-term therapy for maintenance.[11,36,52,53] They may be used as steroid-sparing agents (sequentially or concomitantly with TCS).[36,38]

The most common adverse effect of TCI is transient discomfort (burning sensation) at the application site.[36,38] Some patients may experience a transient worsening of skin conditions; and these transient side effects are more often seen with tacrolimus than pimecrolimus, and if applying to acutely inflamed skin.[36] Generalized viral infections (eg, eczema herpeticum, eczema molluscatum) have been reported.[36] There is a theoretical potential for local skin carcinogenesis as seen in animal studies, or for systemic effects if high blood levels are reached (eg, increased susceptibility to infections due to immunosuppressive effects).[51] Because of the theoretical possible risk of cutaneous malignancy in humans,[36,38] and the known long-term use of systemic cyclosporine being associated with increased photocarcinogenicity in solid organ transplant patients, sun protection is recommended.[11,36,46] However, it may be that the use of TCI has no association with increased risk of nonmelanoma skin cancer, other malignancies, or photocarcinogenicity.[54,55] Nonetheless, patients should be encouraged to apply a high sun protection factor (SPF) broad-spectrum sunblock daily to all exposed skin (ie, SPF 30 or higher); and this counseling should especially be emphasized for those patients with the highest risk of developing skin cancer, including patients with red hair and/or Fitzpatrick skin types I and II, and patients receiving phototherapy or using tanning beds.[46]

TCI are effective in relieving the associated pruritus. Both tacrolimus and pimecrolimus significantly relieve pruritus even after the first few days of treatment, in both children and adults (studies report relief after just 3 days).[10]

Coal Tar

Although tar preparations had been widely used for AD and have been recommended as alternative topical therapy, few RCTs support their efficacy.[38] Their anti-inflammatory properties are not well characterized, and part of the improvement may be the result of a placebo effect, which can be significant in AD.

Coal tar products are also staining and malodorous, although newer products may be more cosmetically acceptable. They are not recommended on acutely inflamed skin, since this may result in additional skin irritation.

The use of coal tar in pregnancy has not been studied. Few data are available about tar excretion into breast milk; in addition, safety in children has not been established.[56] Adverse effects include tar folliculitis, acneiform eruptions, irritant dermatitis, burning, stinging, photosensitivity, and a risk of tar intoxication if used extensively in a young child.[56] Although animal studies showed that tar components can be converted to carcinogenic and mutagenic entities, there is inconclusive epidemiologic evidence supporting the claim that human use of topical tar preparations in dermatology leads to skin cancer.[56]

Selective Phosphodiesterase-4 Inhibitors

Crisaborole and apremilast are small-molecule phosphodiesterase (PDE)-4 inhibitors. Cyclic nucleotide PDEs break down cAMP and cGMP into inactive metabolites and there is increased PDE activity in AD, creating a proinflammatory state that may result in stimulation of Th_2 cells to release inflammatory mediators.[57,58] PDE-4 inhibitors inhibit the increased PDE activity; and crisaborole ointment is FDA approved for treatment of mild-to-moderate AD in adults and children 2 years of age or older.[36] (Apremilast is approved for psoriasis and psoriatic arthritis [see Chapter 118, "Psoriasis," in this textbook].)[57] However, a pilot study of apremilast in patients with moderate-to-severe AD demonstrated moderate improvement of skin lesions, pruritus, and quality of life,[58] and it has also shown success for moderate-to-severe AD in children.[59]

Other Topical Therapies

Patients with moderate-to-severe AD who have frequent bacterial infections may benefit from dilute bleach baths with intranasal mupirocin—one study showed enhanced clinical improvement.[38] Janus kinase (JAK) inhibitors have shown evidence of efficacy for atopic dermatitis when administered either topically and orally. Topical JAK inhibitors include ruxolitinib and tofacitinib.[36]

Phototherapy

⑫ Phototherapy is effective for AD and is recommended[10,11,36,60] as second-line treatment when the disease is not controlled by TCS and/or TCI.[36,60] Although rarely used in prepubertal children, it is not contraindicated.[36] Both natural (heliotherapy) or artificial sources of UV radiation are effective.[36] UV light sources on the skin have immunosuppressive, immunomodulating, anti-inflammatory, and antipruritic effects.[36] A known mechanism of action is immunomodulation through apoptosis of inflammatory cells, inhibition of LCs, and alteration of cytokine production.[36] There are other potential benefits. Phototherapy may be steroid sparing, allowing for the use of lower-potency TCS, or even eliminating the need for maintenance by TCS in some cases. Phototherapy can be used for acute or maintenance therapy in children and adults with AD.[60] Phototherapy may also help prevent secondary bacterial skin infections, commonly seen in patients with AD. UVB radiation reduces *S. aureus* skin colonization.[36,61] However, in a few patients, phototherapy may worsen the AD; it is not recommended in patients whose disease flares up when exposed to sunlight. Relapse following cessation of therapy frequently occurs.[10]

Phototherapy may consist of either ultraviolet light therapy alone, or ultraviolet light therapy alongside drug or topical ointment (commonly called photochemotherapy). Psoralens plus ultraviolet A light (PUVA) is one type of photochemotherapy. The photosensitizer (psoralens) is administered either topically or in a bath immediately prior to ultraviolet A (UVA) light therapy. Topical ointments (such as crude coal tar) may also be used concomitantly with ultraviolet light therapy (eg, Crude coal tar + ultraviolet B [UVB] light) to increase efficacy.

Ultraviolet lamps include UVA (315-400 nm), UVA1 (340-400 nm), broadband UVB (BB-UVB) (280-315 nm), and narrowband UVB (NB-UVB) (311 nm). Phototherapies used for AD have included PUVA, high- or medium-dose UVA1, BB-UVB, and NB-UVB.[10,60] No definitive recommendation can be made to differentiate between the various phototherapies.[60] NB-UVB is more effective than BB-UVB therapy and is generally the most commonly recommended light treatment and it has a better side-effect profile than UVA or PUVA.[10,60] BB-UVB may not effectively treat the scalp and skinfold areas. Medium-dose UVA1 is effective for patients with an acute exacerbation of severe AD; however, the effect may be relatively short-lived and symptoms may recur within 3 months of stopping therapy.[60] Medium-dose UVA1 is considered similar in efficacy as NB-UVB; and high-dose UVA1 is preferred in severe cases when available.[10] There is weaker evidence supporting the use of PUVA in AD[47] and it is not first-choice.[10]

Patients need to wear eye protection during ultraviolet (UV) light therapy to prevent damage to the retina. Short-term adverse effects include erythema, skin pain, skin burning or sunburn, pruritus, and pigmentation.[60] Long-term adverse effects include premature aging of the skin (photoaging), lentigines, photosensitive eruptions, folliculitis, photo-onycholysis, HSV reactivation, facial hypertrichosis, and skin cancer.[60] For example, PUVA has been associated with squamous cell carcinoma and possibly melanoma, which may occur years after PUVA therapy has ceased. UVA therapy may also cause cataract formation.[60]

To minimize a possible initial flare-up, co-medication of TCS and moisturizers has been suggested at the beginning of phototherapy.[36]

Other light therapies include short-wave visible light (>380 nm) ("blue light")—in uncontrolled pilot studies, photopheresis, and devices such as 308-nm monochromatic excimer lasers and pulsed-dye lasers—experimental.[36]

Systemic Therapies

Systemic therapies for the treatment of AD are generally not well studied. Small case series or open studies are available for some agents, but few well-conducted RCTs exist. Agents described in published papers have included systemic corticosteroids, cyclosporine, interferon-γ, azathioprine, methotrexate, mycophenolate mofetil, intravenous immunoglobulin (IVIG), and biologic agents.[10,60] Systemic therapies are indicated in AD care only for the subset of adult and pediatric patients in whom optimized topical regimens and/or phototherapy do not adequately control the disease, or where the quality of life is substantially affected.[60]

Systemic corticosteroids, although sometimes used for rapid disease suppression, are generally not recommended due to an unfavorable risk-benefit profile.[11,36,41,60] A 2017 systematic review of systemic treatment options for adults with AD gave no recommendations for use of systemic corticosteroids due to limited available evidence.[15] The 2018 European consensus guidelines recommended the following regarding oral corticosteroids for patients with AD: (1) restricted use, largely limited to adult patients; (2) short-term use (up to 1 week) in acute flare-ups only in exceptional cases; (3) daily dose not to exceed 0.5 mg/kg bodyweight; (4) use even more cautiously in children than in adults; (5) no long-term use.[36] Short courses of oral corticosteroids may lead to atopic flares/rebound.[11,60]"

Cyclosporine is effective for AD and is considered the first-line treatment option when systemic therapy for AD is warranted, that is, for severe, recalcitrant AD,[10,11,15,36,60] but its usefulness is also limited by significant side effects, including hypertension and nephrotoxicity. Combination with UV therapy is not recommended, and effective UV protection should be used.[36] There is also the potential for significant drug-drug and drug-food (eg, grapefruit juice) interactions. It should be reserved for short-term use in adults (and more cautiously in children) with severe refractory disease.[11,60] Maximal benefit is usually seen after 2 to 6 weeks of use and relapse may occur quickly after cessation of therapy.[10,11,60] Treatment durations recommended are 6 to 9 months[11] and up to 1 year—this is off-label use in the United States and Canada.[60] European guidelines are for 2 years then to switch to another treatment if possible, but shorter intervals of 3 to 6 months are usually recommended; and cyclosporine is approved for AD in many European countries.[36] In a meta-analysis of eight RCTs, cyclosporine was more efficacious than placebo, with reduced body surface area, erythema, sleep loss, and glucocorticoid use. However, all scores were back to pretreatment levels 8 weeks after ending cyclosporine therapy.[10] An earlier study (2000) comparing intermittent to continuous cyclosporine therapy in children 12 to 16 years of age showed efficacy in some children on intermittent therapy (thus with a lower cumulative cyclosporine dose and minimizing toxicity); however, continuous cyclosporine therapy provided enhanced sustained improvement.[36,62]

Recombinant interferon-γ may be effective in a subset of patients with AD.[10] It may be an alternative for refractory AD (adults and children).[60] Two randomized placebo-controlled trials in patients with severe AD demonstrated significant improvement in symptoms.[63,64] Short-term adverse effects, such as headache, myalgias, and chills, occurred in substantial proportions of study patients. Transient liver transaminase elevations and granulocytopenia have also occurred. There is no recommended optimal dose.[60]

Azathioprine,[60,65] *methotrexate,*[60,66] *mycophenolate mofetil,*[60] and IVIG have shown efficacy in small case series or open-label studies primarily in adults with recalcitrant AD. There are two RCTs with azathioprine as monotherapy which showed efficacy, improving both QOL and AD.[60,65] Additional RCTs are needed. Oral methotrexate, with a long history of pediatric use for various inflammatory conditions, is effective in a case series of children (aged 2-16 years) with severe AD[66] and has also shown efficacy in adults.[60]

⑬ *Biologic agents* are beginning to be approved for AD in some countries. The safety and efficacy of various biologic agents in patients with AD have been studied, mostly in case reports, small case series, or open-label studies with a limited number of patients; however, larger randomized, placebo-controlled trials are now available.[36] Dupilumab, a fully human monoclonal antibody that blocks the common α-chain of the receptor for interleukin-4 and intereukin-13, was approved by the FDA in April 2017 for treating moderate-to-severe adult AD.[36] Dupilumab is a down-regulator of the JAK-STAT pathway. Clinical outcomes (SCORAD, EASI, IGA, BSA) as well as patient-reported outcomes (DLQI, pruritus rating scales) were improved in various phase I to III clinical trials in adults with AD.[67] Clinical trials in children are ongoing at the time of writing (NCT02407756) as well as open-label studies evaluating long-term safety and efficacy of repeat doses in children, adolescents, and adults with previous participation in dupilumab clinical trials (NCT02612454, NCT01949311).[15] Dupilumab's safety profile is superior to conventional immunosuppressives such as cyclosporine or methotrexate; its most relevant side effects being conjunctivitis and injection site reactions.[67] Safety in pregnancy is unknown at the time of writing. A recent review of systemic treatment options for adults with AD discussed trials with other biologics including infliximab, mepolizumab, omalizumab, rituximab, and ustekinumab.[15] Some of these trials showed little to no improvement; however, a case series of ustekinumab use showed promising results and was well tolerated.[15] Nemolizumab is another biologic with some promise in a recent clinical trial especially in reducing pruritus.[36] The TNF-α inhibitors infliximab and etanercept is effective in a few patients but not others, and adverse events have included infusion reactions with flushing and dyspnea, urticaria, and recurrent skin infections of methicillin-resistant *S. aureus*. Similarly, omalizumab, rituximab, and alefacept have been shown in a few case reports and small case series to be somewhat effective. A case report series of omalizumab plus IVIG showed significant clinical improvement.[68] However, an RCT with omalizumab showed no clinical improvement in AD despite reducing IgE levels.[60] Therapy of AD with traditional biologics (eg, rituximab, omalizumab, or ustekinumab) is not recommended.[36]

Upadacitinib and abrocitinib are oral selective JAK-1 inhibitors approved by the FDA for treatment of moderate-to-severe atopic dermatitis. Upadacitinib was compared to dupilumab in a 24-week, head-to-head, phase 3b multicenter RCT in adults with moderate-to-severe AD with results showing superior efficacy of upadacitinib vs dupilumab in Eczema Area and Severity Index (EASI75) ($p = 0.006$) and all secondary endpoints such as worst pruritis NRS.[69] There were other clinical trials with upadacitinib involving adults and children older than 12 years, and it has received FDA approval for use at 15 and 30 mg once daily as monotherapy for those age groups. Abrocitinib has received FDA approval based on the results of five clinical trials for use in adults only, at 100 and 200 mg doses, with the 200 mg dose reserved for patients unresponsive to the 100 mg dose. Both products carry a warning of increased risk of serious infections, mortality, malignancy, major adverse cardiovascular events, and thrombosis.

Alitretinoin is a retinoid with anti-inflammatory and antiproliferative effects licensed in some European countries for treatment of hand eczema.[36] It may improve both extrapalmar and hand lesions in AD patients and may be used for atopic hand eczema in adult patients of non-childbearing potential unresponsive to TCS therapy.[36]

Oral antihistamines are used widely; however, there is mixed evidence of efficacy in AD control.[36,60] There is some evidence that oral sedating antihistamines used at night may benefit patients with AD with poor sleep due to pruritus.[11,60]

Complementary and Alternative Therapies

Traditional Chinese herbal therapy has been studied in placebo-controlled trials and provide temporary benefit for patients with severe AD. However, the effectiveness may wear off despite continued treatment, and long-term toxicity is unknown.[10,70] A recent meta-analysis of seven RCTs attempted to evaluate the efficacy and safety of oral Chinese medicines for AD and concluded that traditional Chinese herbal medicines significantly improved symptom severity and was well tolerated; however, the studies were of poor quality and did not allow for valid conclusions to be drawn about tolerability and routine use.[71] Additional studies are needed.

Probiotics and *prebiotics* may prove to be beneficial for prevention and treatment of AD. Probiotics are live microorganisms (bacteria or fungi) that confer a health benefit on the host when administered in adequate amounts.[72] Prebiotics are nondigestable compounds that lead to favorable changes in the gut microbiome.[72] The term "synbiotics" refers to products that contain both probiotics and prebiotics.[72]

Although earlier studies of *probiotics* had mixed results, more recent clinical trials showed evidence of benefit in both prevention and treatment of AD.[72–75] The most common species of probiotics used include *Lactobacillus rhamnosus GG, Lactobacillus casei, Lactobacillus plantarum, Lactobacillus johnsonii, Bifidobacterium lactis*, and *Saccaromues boulardii*.[72] A meta-analysis of 25 clinical trials concluded that probiotics significantly reduced the risk of atopic sensitization when given prenatally.[72,73] A double-blind RCT showed that probiotics reduced the SCORAD index and serum cytokines in

AD patients.[72,74] A randomized trial of oral *Bifidobacterium bifidum* in 40 infants newly diagnosed with AD noted a significant reduction in the SCORAD index posttreatment in the infants receiving the probiotic versus no change in those who did not.[75]

Prebiotics are nondigestible oligosaccharides including fructooligosaccharides, galactooligosaccharides, lactulose, and inulin. These can stimulate the growth of selective beneficial gut bacteria, in particular lactobacilli and bifidobacteria.[72] In the colon, prebiotics are fermented into short chain fatty acids (SCFAs) including butyrate, acetate, and propionate. The SCFAs may alter the gut microbiome. For example, transgalactooligosaccharides increase the number of bifidobacteria and modify the colonic fermentation metabolism of the gut flora.[76] Prebiotics have shown benefits for various disease conditions including hypercholesterolemia, *Clostridium difficile*–associated diarrhea, and allergic conditions such as AD.[72] Two recent meta-analyses have shown a 32% reduced incidence of pediatric AD[77] and that the combination of galactooligosaccharide and fructooligosaccharide reduced AD incidence.[78]

Immunotherapy using allergen-specific desensitization techniques in controlled settings for patients with AD may also be beneficial, and much research is ongoing including RCTs. A recent review and meta-analysis of immunotherapy in patients with AD showed significant efficacy.[11,79] More research is also needed to adequately assess the role of homeopathy, hypnotherapy, acupuncture, massage therapy, and biofeedback therapy in the treatment of AD.

Patient Considerations

⑭ AD may have significant implications not only for the patients themselves, but also their families and caregivers. The burden of AD needs to be addressed. There is strong evidence that AD in adults is associated with select allergic, atopic, immune-mediated, mental health, and bone health comorbidities and skin infections.[37] In addition, patients with refractory AD may need further follow-up to rule out other diagnoses, confirm adequate/appropriate first-line therapy use, rule out/minimize exacerbating factors, and implement second-line therapies.[80]

In 2006, an international study of 2,002 patients and caregivers from eight countries addressed the effect of AD on the lives of patients and society.[81] This European study found that, on average, patients experienced nine flares per year, with those having severe disease experiencing more flares and taking significantly longer to clear. The flares were associated with disturbed sleep, and 86% of patients avoided at least one type of everyday activity. Schoolwork performance and productivity were negatively affected. Patients missed an average of 2.5 days of school or work per year, and an analysis of adult patient performance at work and occupational absence showed that the social cost of lost productivity could amount to more than 2 billion Euros per year across the European Union. There were also emotional consequences; half of the patients experienced depression or unhappiness about their condition, and one-third reported that AD had eroded their self-confidence. In addition, concern about adverse effects from TCS treatments resulted in poor adherence to therapy. On average, patients endured the symptoms of AD without initiating specific treatment 47% of the time they had an exacerbation. Approximately one-half of the respondents were concerned about using TCS, and 58% restricted them to particular sites, 39% used them less frequently or for shorter time periods than prescribed, and 66% used them as a last resort. The study concluded that AD is "an undertreated disease that has a significant, yet mostly avoidable, negative effect on patients, their caregivers, and society."[81]

The above conclusion is echoed in more recent reports. In 2018 and 2019, studies relating to the burden of disease from the United States, Canada, and internationally were published. In a 2018 US cross-sectional study, 1,519 adult patients with AD reported a multidimensional burden of disease that is higher with greater disease severity and inadequate disease control.[82] Patients with moderate/severe AD (830/1519) reported more severe itching and pain, greater adverse effects on sleep, higher prevalence of anxiety and depression, and greater health-related QoL impairment. About 103/1,519 patients had inadequate disease control despite treatment with systemic immunomodulators or phototherapy, and they reported higher burdens of itch and sleeping symptoms versus those with controlled disease.[82] Sleep symptoms included trouble sleeping (significant on PO-SCORAD), longer sleep latency, more frequent sleep disturbances, and greater need for OTC sleep medications.[82] Results from two 2018 Canadian online national cross-sectional surveys included the burden of moderate-to-severe AD on pediatric patients.[83] For the adult patients: 87% (187/216) reported that their daily life was negatively affected by their disease, with experiences ranging from dysfunctional sleep (79%, ie, 148/187), anxiety (64%, ie, 120/187), avoidance of social activities (48%, ie, 90/187), avoidance of physical activity (47%, ie, 88/187), and avoidance of intimacy (40%, ie, 75/187). In addition, 32% reported difficulty accessing treatments and 41% felt that their treatment needs were unmet. Only 9% reported that their disease was well controlled, and 78% reported they had lived for over one year with inadequate treatment for their disease. For the pediatric patients: 78% (253/361) had sleep disturbances, 51% avoided social activities, 30% had anxiety issues, 20% missed school due to their AD—and of these, 23%

have missed 10 days or more within the past year.[83] Regardless of treatment modalities, most survey respondents felt that their child's AD is not well controlled—85% have used three or more treatment modalities for their child's AD, and 80% of respondents find the recommended care regimen for their child's AD challenging.[83]

In 2019, data from a 2016 National Health and Wellness Survey conducted in France, Germany, Italy, Spain, and the United Kingdom was published with comparisons between controls without AD matched to patients with self-reported AD (both $n = 1{,}860$).[84] Self-reported comorbidities were significantly more prevalent in patients with AD compared to those without AD and these included anxiety, depression, and sleep disturbances. There was reduced health-related QoL as well as a significant impact on work productivity (ie, presenteeism and overall work impairment) and the ability to undertake activities. There was also greater healthcare utilization.[84]

Even though there is likely selection bias due to the self-reporting nature of these surveys, the results from these (and others) should alert healthcare professionals to the continuing unmet health, psychosocial, and educational needs associated with AD.

Patient communication may be a key step—treating them as partners in their own (or their child's) care, with regular contact, advice, and support. Healthcare professionals play an integral role in providing patient and caregiver education and support about this disease and specific treatment plans. The importance of adequate and appropriate education for the patient, family, and caregivers about AD and its management cannot be overemphasized. Patients should be involved in their own care whenever possible. Timely access to dermatology consultation may be another key factor—in the above Canadian survey only 27% (123/451) of respondents are managed by a dermatologist—wait times for appointments were 3 months or longer (46%) and in 25% of cases were 6 months or longer.[81] Limited access to care is a societal issue.

EVALUATION OF THERAPEUTIC OUTCOMES

- Contact patient/caregiver in 1 to 2 weeks to follow-up about the efficacy of recommended therapies and any issues with the treatment regimen. Continuing regular follow-up is recommended to monitor for adherence and address other issues and patient concerns (eg, QoL issues as discussed above).
- Ensure that appropriate monitoring parameters for efficacy and potential adverse effects have been put in place (eg, follow-up lab tests as needed).
- Reinforce preventive measures including continuation of proactive therapy, if implemented.
- Ensure that patient/caregiver has been connected to other health resources as needed for follow-up (eg, a dermatologist, psychologist, and social worker).

CONCLUSION

AD is a chronic skin condition that generally presents at an early age. It affects the patient, family, caregivers, and our society and is optimally managed by multidisciplinary care. Nonpharmacologic management strategies are important in treatment; these include appropriate skin care, hydration, avoidance of triggers, and psychosocial support and management. Community pharmacists are in a prime position to support patients, physicians, and other health professionals because patients with AD (and caregivers of children with AD) may initially seek nonprescription treatments.[30] The pharmacologic treatment strategy may be proactive or reactive depending on disease severity. Treatment alternatives continue to emphasize TCS as the standard of care; others being TCIs and other topical agents, wet wrap therapy, and UV therapy. For severe/recalcitrant disease, systemic therapies including cyclosporine and biologics may be warranted. A 2018 review provides a step-wise clinical approach to the patient with refractory AD which include ruling out other diagnoses, confirming first-line therapies, and ruling out exacerbating factors before using second-line therapies; further, a multidisciplinary approach to address behavioral factors (poor adherence, improper technique, habitual scratching, depression, sleep disturbance, stress) is described (eg, habit reversal training for the itch-scratch cycle).[80] Patient and caregiver education and support about AD and treatment strategies is critical to optimize treatment outcomes. Successful outcomes result when patients and caregivers are partners with healthcare professionals in the management of this chronic disease.

ACKNOWLEDGMENT

The authors gratefully acknowledge the contributions of Dr. P.G. Kwa to previous editions of this chapter.[1]

ABBREVIATIONS

AD	atopic dermatitis

SELF-ASSESSMENT QUESTIONS

1. Baby JS is a 7-month-old infant who has been diagnosed with atopic dermatitis. Clinical signs and symptoms she presented with may include all the following EXCEPT:

   A. Pruritus

   B. Hypopigmentation

   C. Facial eruptions

   D. Secondary bacterial infection

2. Appropriate nonpharmacologic therapy for Baby JS (7 months of age) includes all of the following EXCEPT:

   A. Moisturizer applied *ad lib*

   B. Bathing five times a day

   C. Keep humidity at or above 50%

   D. Keep June cool—avoid situations of overheating

3. Initial pharmacologic therapy for Baby JS (7 months of age) should be:

   A. Topical corticosteroid

   B. Topical pimecrolimus

   C. Oral prednisone

   D. Phototherapy with UVB

4. The defect thought to play a key role in atopic dermatitis is:

   A. Mutations of the filaggrin gene

   B. Absence of the epidermal growth hormone

   C. Presence of the Philadelphia chromosome

   D. Abnormal CFTR protein

5. An immune system change associated with atopic dermatitis is:

   A. Reduced serum IgE

   B. Increased interleukin-12

C. Increased Th_2 cell activity

D. Increased blood neutrophils

6. Miss SB is a 15-year-old girl with atopic dermatitis who has multiple food allergies. The most allergenic foods that Susanne might be allergic to would include all of the following EXCEPT:

A. Eggs

B. Milk

C. Bananas

D. Strawberries

7. Miss SB (15-year-old girl with atopic dermatitis) was assessed for disease severity by her dermatologist—who used the SCORAD. She has significant pruritus and her sleep was generally restless with multiple wakenings during the night. Her SCORAD score was 40. This means that Susanne's atopic dermatitis is:

A. Mild

B. Moderate

C. Severe

D. Very severe

8. Miss SB (15-year-old girl with atopic dermatitis) also has yellow crusting lesions on her skin which was diagnosed as a bacterial infection. The most likely organism is:

A. *Staphylococcus aureus*

B. *Pseudomonas aeruginosa*

C. *Streptococcus viridians*

D. *Xenotrophomonas maltophilia*

9. Miss SB (15-year-old girl with atopic dermatitis) has required pimecrolimus 1% cream during her flare-ups. Appropriate counseling for SB would include:

A. Apply the cream only on lichenified areas

B. Use the cream three to four times a day

C. It is very uncommon for the cream to cause a burning sensation

D. Wear a sunscreen with SPF 30 or higher

10. Which of the following treatment alternative would be preferred in a pregnant patient with atopic dermatitis?

A. Topical corticosteroid

B. Oral cyclosporine

C. Injectable dupilumab

D. Phototherapy with PUVA

11. The most effective type of phototherapy for atopic dermatitis is:

    A. Broadband UVB

    B. Narrowband UVB

    C. PUVA

    D. Low-dose UVA

12. Potential concerns with biologic agents (eg, dupilumab) include all of the following EXCEPT:

    A. Allergic reactions

    B. Infections

    C. Carcinogenesis

    D. Skin atrophy

13. Potential concerns with oral cyclosporine include all of the following EXCEPT:

    A. Hypertension

    B. Nephrotoxicity

    C. Hepatotoxicity

    D. Interaction with grapefruit juice

14. Ultrahigh- and high-potency topical corticosteroids include all of the following EXCEPT:

    A. Betamethasone valerate

    B. Betamethasone dipropionate

    C. Clobetasone propionate

    D. Diflorasone diacetate

15. Appropriate use of oral prednisone for atopic dermatitis include all of the following EXCEPT:

    A. For severe, recalcitrant, chronic atopic dermatitis

    B. For rapid relief of severe refractory disease while transitioning to other therapies

    C. Discontinue abruptly after a short 5-day course

    D. Provide intensified skin care with topical corticosteroids and moisturizers

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** Hypopigmentation is not a feature of AD, the others are.

2. **B.** Bathing should usually not be more often than once (to twice) a day.

3. **A.** Topical corticosteroids remain the treatment of choice for AD. Calcineurin inhibitors such as pimecrolimus are second-line, but in this case of a 7-

month-old they would not be recommended.

4. **A.** FLG mutations remain the most significant defect in AD.

5. **C**. Increased TH_2 activity is a significant pathophysiologic change in AD.

6. **C**. The other foods are more often associated with AD/seen in patients with food allergies.

7. **B**. A SCORAD score between 25 and 50 is considered moderate disease.

8. **A.** *Staphylococcus epidermidis* (coagulative negative Staph) is a skin commensal and most likely to be the causative agent.

9. **D.** This relates to the potential concern of skin carcinogenesis and possibly increased risk with sun exposure. Thus, sunscreen use (SPF >30) is recommended.

10. **A**. Topical corticosteroid is first-line therapy for AD including in pregnancy. The others are systemic therapies or have a systemic component (PUVA), thus greater risk to the baby. Corticosteroids are safe to use in pregnancy.

11. **B**. NB-UVB is the most effective and least toxic.

12. **D.** The other options are potential side effects/toxicity of biologic agents.

13. **C.** Oral cyclosporine may be nephrotoxic but not hepatotoxic.

14. **A.** Betamethasone *valerate* is a midpotency corticosteroid. Note that the salt makes a difference to corticosteroid potency.

15. **C.** Abrupt disruption may result in a disease flare.

Chapter 120: Alopecia

Rebecca M. Law; Le Hanh Dung Do; Howard I. Maibach

KEY CONCEPTS

KEY CONCEPTS

① The hair cycle consists of three phases: anagen, catagen, and telogen. These are not synchronized across all hair follicles. Different factors regulate each phase of the hair cycle.

② Pattern hair loss (or androgenetic alopecia) is an inherited condition in which androgens play a key role.

③ Inflammation plays an important role in alopecia. Inflammatory infiltrates are evident in androgenetic alopecia and alopecia areata. Alopecia areata is the most frequent cause of inflammation-induced alopecia. Chronic inflammation may lead to the destruction of the hair follicle, resulting in irreversible hair loss.

④ Scarring hair loss (or cicatricial alopecia) leading to irreversible hair loss can be caused by chronic inflammation or secondary to burns, cancer, trauma, radiation, or other diseases such as lichen planopilaris and chronic cutaneous lupus erythematosus.

⑤ Thinning of hair or hair loss is usually the only clinical sign of alopecia. Other symptoms (eg, itching, pain, burning, or prickly discomfort) would suggest other underlying disease conditions. Dermatologic diseases can cause hair loss, which varies from mild, nonscarring, and reversible to scarring and irreversible.

⑥ Alopecia can be distressing, affecting the quality of life and causing psychological problems. Psychosocial support and counseling must not be overlooked.

⑦ Treatment and management strategies of alopecia should be as cause-specific as possible. Identified causes (eg, iron deficiency, tinea capitis) should be treated and/or eliminated as soon as practically feasible.

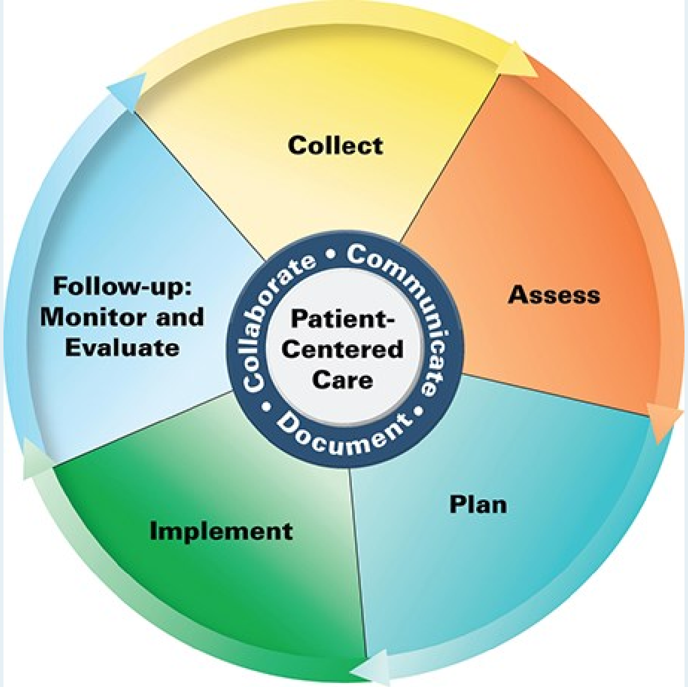
⑧ Treatment for androgenetic alopecia includes topical minoxidil, oral 5α-reductase inhibitors (finasteride, dutasteride) for men, hormonal therapy for women, and miscellaneous therapies including nutritional supplements and laser light therapy with variable efficacy.

⑨ Treatment for alopecia areata includes intralesional corticosteroids, topical corticosteroids, high-dose oral corticosteroids, topical minoxidil, topical immunotherapy, topical and systemic biologic agents (in particular JAK inhibitors), azathioprine and other immunosuppressive agents, and other miscellaneous therapies.

⑩ Treatment of alopecia in patients of color should include cultural sensitivity for hair stigma (patient hair differs from perceived societal norm) and hair discordance (racial discordance between health professionals and patients seeking care for alopecia).

PATIENT CARE PROCESS

Patient Care Process for Androgenetic Alopecia



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex, pregnancy status if female)
- Patient medical history (personal and family)
- Patient description of history of the alopecia
- Signs associated with severity of androgenetic alopecia (eg, areas of involvement)
- Signs or symptoms of other conditions (ie, differential diagnosis—could this be a condition other than androgenetic alopecia? Symptoms such as itching, pain, burning, or prickly discomfort may suggest underlying conditions. If the alopecia is seen in a female, is polycystic ovarian syndrome [PCOS] or congenital adrenal hyperplasia present?)

Assess

- Severity of androgenetic alopecia—can quantify using hair counts, hair density measurements, and assessing the areas of involvement
- Relevant lab work, if needed (eg, check parameters that would rule out PCOS. Refer to the Acne case in the Casebook for discussion of relevant labs for PCOS.)
- Ability/willingness to pay for treatment options
- Emotional/psychological concerns

Plan

- Determine an appropriate treatment approach or various optional approaches (ie, topical vs systemic pharmacotherapy vs natural health products/nutritional supplements vs other approaches [mesotherapy, low-level laser light therapy, hair restoration surgery, cosmetic coverings]). Determine if psychosocial support is needed.
- Discuss with the patient various options to determine the most appropriate therapies (nonpharmacologic and pharmacologic) for the patient. Discuss options for psychosocial support if needed.

Implement*

- Provide patient education regarding all elements of treatment plan. Patient counseling points for various agents follow.
  - If topical therapy with minoxidil lotion is used: (1) Transient hair shedding may initially occur (indicating that minoxidil is stimulating hair follicles to re-enter a growth phase called anagen). This usually normalizes within a few weeks to months of starting therapy and treatment should be continued and not stopped. (2) To minimize drug contamination of the pillow and then inadvertent transfer to the face during sleep, use minoxidil lotion at least 2 hours before going to bed.
  - If systemic therapy with finasteride or dutasteride is used: (1) The medication must be swallowed whole and not chewed or crushed. (2) The medication may harm a growing fetus; pregnant women should not ingest or touch broken tablets. This also includes women seeking to become pregnant (including pharmacists, other health professionals, and caregivers). (3) The medication may cause sexual dysfunction. (4) Bloodwork may be needed (liver function tests) to monitor for potential side effects. (5) There are potential interactions with other medications—please check with your physician or pharmacist.
- Use motivational interviewing and coaching strategies to maximize adherence when needed.
- Provide information about prevention/minimization of further hair loss (eg, appropriate hair care). Provide information about psychosocial support options, if needed.

Follow-up: Monitor and Evaluate

- Contact patient in 3 and 6 months to follow-up about the efficacy of recommended therapies and any issues with the treatment regimen.
- Ensure that appropriate monitoring parameters for efficacy and potential adverse effects have been put in place. Ensure follow-up lab tests if needed are in place (eg, liver function tests when finasteride or dutasteride is used).
- Reinforce preventive measures including appropriate hair care.

**Collaborate with patient, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Read this continuing medical education article: “Hair Loss: Common Causes and Treatment,” by T. Grant Phillips, W. P. Slomiany, and R. Allison.[1]

INTRODUCTION

Having a full head of hair is of some importance to most adults and children. Alopecia, defined in the Oxford Dictionary as “the partial or complete absence of hair from areas of the body where it normally grows,” is a condition with a myriad of causes. This chapter reviews normal hair growth and physiology and discusses some of the known causes and types of alopecia.

ANATOMY AND PHYSIOLOGY OF THE HAIR FOLLICLE

Hair covers most of the human body and grows both outside and inside of the skin. The external part is keratinized nonliving hair shaft, and the living follicles are located below the skin surface. The visible dead shaft mostly remains constant, while the living follicles continuously regenerate.[2,3]

The hair follicle is part of the human skin. It begins in the dermis with the hair bulb and the hair shaft, which extend through the epidermis and out into the external environment. The dermis provides support for the hair bulb, hair shaft, and other skin structures and appendages. The hair follicle and the sebaceous gland form a pilosebaceous unit with a common duct opening into the environment (Fig. 120-1). (For discussions of other components in skin, refer to Chapter e121, "Drug-Induced Dermatologic Disorders.")

FIGURE 120-1

The hair shaft comprises three layers from outside to inside: the cuticle, the cortex, and the medulla. The cuticle consists of hard, colorless cells that overlap. This outermost layer is responsible for elasticity and resiliency; it determines the general condition of the hair. The cortex contains melanin and thus determines hair color. It also contains keratin and determines whether the hair is straight or curly. The innermost layer is the medulla, which plays an important role in supporting the structure of hair.

Below the skin surface, the hair follicle is divided into upper and lower segments by the insertion site of the arrector pili muscle. The upper segment comprises the infundibulum and the isthmus (Fig. 120-2). The infundibulum is a funnel-shaped cavity that serves as a reservoir of the sebaceous gland. It is filled with sebum, and covered by an impermeable stratum corneum. The isthmus lies below the infundibulum, and it connects the duct of the sebaceous gland to the arrector pili muscle. The lower segment of the hair follicle contains the stem and the hair bulb. Adamson's fringe is the boundary between anucleate cells in the stem and nucleated cells in the bulb. The hair bulb contains nerve fibers, a capillary network, and loose connective tissue called the dermal papilla. Nerves and arterioles that supply the follicles are arranged as a plexus, arising from the subcutaneous fat to the dermis. The dermal papilla is a pear-shaped structure that consists of active cells and growth factors, which can induce hair growth and pigmentation.

The Hair Cycle

① The hair cycle consists of three phases; these are not synchronized among all hair follicles. The phases are the anagen, catagen, and telogen phases, followed by an intermediary "returning to anagen" phase (Fig. 120-3).[4]

FIGURE 120-3

Most of the hairs are in the *anagen phase* (also known as the growth phase). At the beginning of this phase, hair stem cells multiply, grow downward into the dermis, and differentiate into the hair shaft,[5] where the melanocytes start producing pigment. While the anagen phase of short hairs (eg, eyelashes, eyebrows, hairs on arms, and legs) lasts around 1 month, those of longer scalp hairs can last up to 6 years. Scalp hairs of an adult grow at a rate of about 1 mm per 3 days.

The anagen phase is regulated by factors as listed in column 1 of Table 120-1. Since hairs in this phase are growing, regulation is mostly by growth factors.

TABLE 120-1

Regulatory Factors of Three Phases in the Hair Cycle

Anagen Phase	Catagen Phase	Telogen Phase
Bone morphogenetic protein (BMP)	FGF-5	Androgens
Sonic hedgehog	Transforming growth factor β1 (TG F-β1)	Prolactin
WNT proteins and receptors	Interleukin 1b (IL-1b)	Adrenocorticotropic hormone (ACT H)
Insulin-like growth factor-1 (IGF-1)	Neurotrophins NT-3, NT-4	Retinoids and thyroid hormones
Fibroblast growth factor-7 (FGF-7)	Bone morphogenetic protein BMP2/4	Estrogen
Hepatic growth factor (HGF)	Tumor necrosis factor α (TNF-α)	FGF-5
Vascular endothelial growth factor (VEGF)		BMP-4[6]

Overall, about 1% to 3% of hairs are in the *catagen phase* (also known as the transition phase). It begins when the anagen phase ends. The hair follicle starts to undergo apoptosis and reduces in size. The keratinocytes decrease proliferation, melanocytes decrease the production of pigments, and the hair shaft is no longer lengthened. The dermal papilla is transformed into a cluster of inactive cells along with the shrinking hair follicle. This phase lasts about 2 to 3 weeks.

The catagen phase is regulated by factors as listed in column 2 of Table 120-1.[7] Note that Interleukin 1b (IL-1b) and tumor necrosis factor α (TNF-α) aid the inhibition of growth factors, leading to a decrease in proliferation of hair follicles.

The *telogen phase* begins after the catagen phase ends and lasts for 1 to 3 months, with 10% to 15% of hairs. The hair and the dermal papilla go into a resting phase and melanocytes go into apoptosis.

This phase is regulated by various hormones (thyroid hormones, androgens, prolactin, ACTH, and others) as listed in column 3 of Table 120-1. In the end, the hair falls out (*exogen phase*) at a usual rate of 50 to 100 scalp hairs per day.

The follicle rests for a few weeks and then proceeds to the growth phase with the multipotent stem cells from the bulge area. Generally, hair grows until the fourth decade of life. After that age period, the majority of hair follicles are in the catagen and telogen phases, which leads to thinning of the hair, and baldness.

PATHOPHYSIOLOGY

Hormones

② Androgens play a key role in pattern hair loss, which is an inherited condition characterized by scalp sensitivity to dihydrotestosterone (DHT). Testosterone is converted into DHT by the enzyme 5α-reductase. DHT binds to androgen receptors in the same manner as testosterone, but with much greater affinity. DHT shortens the telogen phase, leading to more rapid hair loss. With aging, new hairs become insufficient to replace the shed ones and contribute to alopecia. This mechanism is observed both in male and female pattern hair loss. Treatment protocols for alopecia using inhibitors of 5α-reductase are proven to be effective.[8]

Genetic Association

② In the 1990s and early 2000s, observations that there is a resemblance between alopecia in fathers and sons led to suggestions that genes from some autosomal chromosomes were the cause of male pattern baldness. Postulated genes included the insulin gene, the 5α-reductase genes, and the hairless gene.[9] However, further investigations[10-12] found only a weak association between those genes and male pattern alopecia.

Maternal inheritance of male pattern alopecia with their investigation of variants of androgen receptor locus on the X chromosome was demonstrated.[13] This implied that the phenotypic resemblance should be higher between affected males and their maternal grandfathers than between affected males and their fathers. However, the attributable risk from this case–control study was only 0.46, which indicated that the remaining risk fraction was due to other autosomal loci, which may explain the similarity of the alopecia pattern between fathers and sons.

Genetic predisposition has been shown for alopecia areata (AA) through a genome-wide association study that identified eight susceptibility loci and 139 single-nucleotide polymorphisms associated with the activation and proliferation of T-cells, IL-2 receptors, natural killer cell receptors, genes expressed in the hair follicle, and other factors.[14] A follow-up study established IL-13 and KIAA0350/CLEC16A as susceptibility loci for AA.[15] Research is ongoing.

Hair Cycle Dynamics

The hair cycle itself was one of the key factors in alopecia.[16] As mentioned above, maximal hair length is achieved in the *anagen phase*. If this phase is too short, patients may present with shortened hair. In some cases, the *anagen* duration may significantly decline, which may lead to empty follicular pores.[17] A shortened *anagen phase* leads to a premature progression to the *telogen phase*, which contributes to a decrease in hair diameter (clinically seen as fine hair) and hair loss. Patients also present with longer duration of the *telogen phase* and latency to the next hair cycle. This lag worsens the effect of alopecia.

Inflammation

③ Inflammation plays an important role in alopecia. Lymphohistiocytic infiltrate in the perifollicular area was shown, with collagen deposition four times higher in patients with male pattern alopecia than in normal controls.[18] Morphometric and ultrastructural analyses of the transitional zones in patients with male pattern alopecia were performed and found a significant increase in the number of mast cells and lymphocytes around the follicular epithelium.[19]

A study in 2012 also showed greater eosinophilic infiltration around lower hair follicles and mononuclear cell count in diffuse AA.[20] A 2012 review described AA as an autoimmune inflammatory disorder in which hair follicles are attacked by a mixed inflammatory cell infiltrate containing T-cells, natural killer cells, mast cells, and dendritic cells.[4]

Scarring

③ Chronic inflammation may lead to the destruction of the hair follicle and irreversible hair loss.[21] In this case, the hair follicle is replaced by fibrous tissue and the epithelial stem cells in the bulge are destroyed, leading to the hair follicle losing the ability to regenerate.[22]

④ Scarring alopecia (or cicatricial alopecia) leading to irreversible hair loss can be caused by chronic inflammation or secondary to burns, cancer, trauma, radiation, or other diseases such as lichen planopilaris and chronic cutaneous lupus erythematosus. This type of scarring alopecia is discussed further in the “Scarring Hair Loss” section.

CLINICAL PRESENTATION

⑤ Thinning of hair or hair loss is usually the only sign of alopecia. Other symptoms such as itching, pain, burning, or prickly discomfort may suggest other underlying conditions.

Anagen Hair Loss

Anagen hair loss or anagen effluvium usually has a sudden onset.[23] Patients present with the chief complaint of short hair and the inability to grow longer hair. The hair can be thin, sparse, but usually not fragile. Empty follicles can also be seen. Most cases of anagen effluvium are reversible and hair can regrow in 6 months. Common causes and presentations of anagen effluvium are listed in Table 120-2.

TABLE 120-2

Characteristics of Hair Loss in Anagen Effluvium

Causes	Presentations
Autoimmune disease—severe diffuse alopecia areata[20]	Diffuse and rapid hair shedding with exclamation point hairs, usually starts with a round patch, then spreads in a multilocular pattern.
Chemotherapy-induced alopecia[24]	Patients who recently received anticancer chemotherapeutic agents, radiation treatment, and other medications. Not all anticancer agents/treatments cause hair loss.
	Usually, recovery occurs within 6 months of treatment completion/drug discontinuation.
Inherited/congenital condition—loose anagen syndrome[25]	Predominantly seen in young girls between 2 and 6 years, but sometimes in boys. Diffuse or patchy alopecia often seen in the occiput.

Telogen Hair Loss

Telogen hair loss or telogen effluvium starts with thinning of hair, especially at the temples. It is a noninflammatory alopecia, usually of sudden onset.[2] Patients can lose 300 to 500 hairs a day, which is 2 to 3 times more than usual hair loss in a healthy individual. Hairs appear to be short, thin, and lacking melanin.

Telogen effluvium is usually seen 3 months after a medical condition that stops hair growth, such as childbirth, surgery, hormonal imbalance, or medications. The *telogen phase* normally lasts for about 3 months; if the condition is caused by drugs, hair can regrow after 4 months of drug withdrawal. The various systemic medical conditions affect the scalp, resulting in nonscarring alopecia. Medical causes include iron deficiency, thyroid hormone deficiency, systemic lupus erythematosus, syphilis, bacterial infections, and viral infection (herpes zoster). Medical and other causes are listed in Table 120-3.

TABLE 120-3

Causes of Telogen Effluvium

Pregnancy
Psychological stress
Fever, infection, hemorrhage, surgery
Weight loss
Autoimmune diseases (most common is systemic lupus erythematosus), thyroid hormone deficiency
Localized telogen effluvium following hair transplantation[26]
Vitamin or mineral deficiency—iron deficiency is a common cause of hair loss in women
Medications: contraceptives, anticoagulants, anticonvulsants, isotretinoin, warfarin

Androgenetic Alopecia

Distinct patterns of hair loss are seen in boys/men and girls/women (Table 120-4).

TABLE 120-4

Male and Female Pattern Hair Loss

Male Pattern Hair Loss	Female Pattern Hair Loss
Gradual loss of the frontal hairline early in the process.	The frontal hairline is often preserved. Gradual thinning leading to widening of the part line.
Gradual thinning in the vertex and temporal areas.	Thinning hair on the mid-frontal area of the scalp. Diffuse pattern. Hair loss is generally less severe than that which occurs in males.

② Male pattern hair loss, or androgenetic alopecia (AGA), is the most common type of hair loss; it most often occurs in adult males.[23] AGA is caused by the effects of DHT in specific areas of the scalp such as the vertex and the temporal scalp. Patients usually have a vivid memory of a transitional time from having thick, long pigmented hairs to thinner, shorter hairs with less pigment.

A few women present with male pattern hair loss (AGA) caused by excessive levels of androgens, which leads to thinning hair on the mid-frontal area, but the condition is usually milder than in men. Polycystic ovarian syndrome (PCOS) and congenital adrenal hyperplasia are the common causes of male pattern hair loss in women.

Female pattern hair loss (FPHL or female AGA) usually presents with preservation of the frontal hairline with widening of the part line and reduced hair volume. These women are mostly losing their hair with age and hormone tests are normal. The Ludwig Classification is often used to describe FPHL, with Type I being minimal thinning that can be camouflaged with hair styling techniques and Type III being diffuse thinning with a see-through appearance on the top of the scalp.[27]

Dermatological Disease

③④⑤ Dermatological conditions on the scalp may result in scarring or nonscarring patchy hair thinning and alopecia. Table 120-5 provides some common diseases and their presentations.

TABLE 120-5

Dermatological Diseases That Can Cause Hair Loss

Diseases	Presentations
Tinea capitis[28]	Gray patch (scaling with patchy hair loss), black dot, and diffuseal opecia. But on occasions, severely inflammatory and raised lesions can occur.
Psoriatic alopecia[29]	Often nonscarring and regrows after a few months. Complete destruction of the follicle leads to the inability to regrow.
Seborrheic dermatitis of the scalp[30]	From mild desquamation to honey-colored crusts attached to scalp and hair leading to alopecia. May reach into forehead as scaly erythematous border known as "corona seborrheica."
Allergic contact dermatitis of the scalp[31]	Mild hair loss 2-4 months after the episode of scalp dermatitis.
Pityriasis rubra pilaris[32]	Eczematous changes of the skin, ichthyosiform scale on lower extremities, coarse laminated palmoplantar keratoderma, and alopecia.
Erythroderma (a generalized disease)	Generalized erythema and exfoliation, patients sometimes present with malaise, fever or hypothermia, pruritus, diffuse alopecia, keratoderma, nail dystrophy, ectropion, pitting edema, lymphade nopathy, tachycardia, and high-output cardiac failure.[33]

Scarring Hair Loss

③ ④ Scarring hair loss, or cicatricial alopecia, can be primary or secondary to indirect causes, such as burns, cancer, trauma, or radiation. Table 120-6 provides common causes of scarring hair loss and their presentations.

TABLE 120-6

Characteristics of Scarring Hair Loss

Causes	Presentations
Lichen planopilaris	<10% scalp involvement (localized) Generalized Rapidly progressing Itchy, multifocal, or central patches with follicular hyperke ratosis and perifollicular erythema; nonscalp areas may be affected
Chronic cutaneous lupus erythematosus	Single or multifocal patches with pronounced activity in the center of the patch, ulceration, follicular plugging, atrophy, and depigmentation
Frontal fibrosing alopecia	Band-like distribution around the frontal hairline; may be present in eyebrows
Central centrifugal cicatricial alopecia	Resembles lichen planopilaris; burning, scaling, and itchiness may occur
Brocq pseudopelade	Small and/or large, irregular patches of hair loss on the scalp with no detectable symptoms or inflammation; end-stage burnout
Folliculitis decalvans	Single patch of complete alopecia that expands circumferentially, slowly over years; typically found on hair-bearing p eriphery of scalp; pustules, honey-colored crusting, tufting; nonscalp involvement is rare
Dissecting cellulitis of the scalp	Multiple fluctuant nodules found across the scalp, often interconnected by sinus tracts; may be associated with acne conglobata: discharge is common and should be cultured

Alopecia Areata

③ Alopecia areata (AA) is the most frequent cause of inflammation-induced hair loss, affecting perhaps 4.5 million people in the United States.[4] AA affects both children and adults, with prevalence rates peaking between the ages of 20 and 40 years; up to 66% of AA patients are younger than 30 years and only 20% are older than 40 years.[4] Although AA generally occurs equally in males and females,[4,34] one study involving subjects 21 to 30 years found male dominance.[35]

AA is a nonscarring, autoimmune inflammatory disease that manifests in the hair follicles and can affect the nails in up to two-thirds of patients.[36] Due to the autoimmune nature of the disease, hair-follicle specific autoantibodies may be detected and other autoimmune conditions may be associated. There is a familial tendency with an especially high concordance rate in monozygotic twins, and genetic polymorphisms have been identified in multiple regions of the human genome.[34]

AA presents as an acute, patchy alopecia (with a well-circumscribed solitary or multiple patches) that is most commonly seen on the scalp but can be elsewhere in the body.[36,37] Patches up to 2 cm (~0.8 in.) in diameter can suddenly appear overnight then extend circumferentially at a rate of about 1 cm/week (0.4 in./week); the hair loss consists of hair breakage close to or just below the skin surface. As a result, black dots can be seen on dermoscopy, with characteristic "exclamation mark" hairs—that is, hairs where the distal hair shaft is broader than the proximal end—around the margins of the patch of hair loss.[4] Table 120-7 lists the types of AA.

TABLE 120-7

Classifications of Alopecia Areata

Types	Descriptions
Patchy AA	The most common type; localized hair loss; patchy; most commonly on scalp, sometimes involving beard area
AA totalis	Total hair loss on the scalp
AA universalis	Complete hair loss in all hair-bearing areas
Acute diffuse and total alopecia	Short clinical course ranging from a little hair loss to total baldness; favorable prognosis; rapid disease resolution, sometimes without treatment
Diffuse AA	Diffuse hair loss; can mimic telogen effluvium
Ophiasis	Hair loss only on the sides of the scalp (occipital areas) and the nape
Sisapho	A rare condition in which hair loss spares the sides of the scalp (occipital areas) and the nape and usually affects the central scalphis
Reticular patches	Several patches of AA coalescing to form a reticular pattern

Data from References 4,34.

AA involves abnormality in the hair cycle (shortened and disordered) due to the activity of inflammatory mediators released by a mixed inflammatory cell infiltrate (Fig. 120-4).[4]

Alopecia in Children

Hair loss in the pediatric population is more common than expected—about 7.5% of pediatric patients in dermatology practices.[38] Although sharing many features with alopecia in adults, children may present with unique associations that require further examination.

A 5-year study in Jordan[38] showed that the three most common causes of alopecia in children are tinea capitis (40.5%), AA (17.6%), and telogen effluvium (17%). Tinea capitis is often straightforward with additional findings, such as itchy erythema and scaly border. However, in some communities, parents use unknown topical/herbal creams, some of which contain corticosteroids, and these can mask the presentation of tinea capitis. Therefore, potassium hydroxide (KOH) testing plays an important role in etiologic diagnosis.

Autoimmune diseases were found in 13.5% of the pediatric AA cases, including diabetes, hypothyroidism, and vitiligo. In pediatric AA, the male:female ratio is 3:2,[38] compared to 1:2.3 in adults.[39]

Telogen effluvium in children is commonly caused by a prior low-grade fever.[38] All of these cases presented with a healthy scalp, normal hair texture, and regular bulb of telogen hair. This condition was seen more in female children, usually within 4 to 6 months before coming to the clinic.

Approximately 20% of the examined cases had some elements of traction alopecia,[38] with female predominance and occurring at the hairline. Moreover, some cases showed follicular pustules and perifollicular inflammation. This type of hair loss may be more common than the 20% seen, as traction alopecia is easily noticed by parents and reversed by wearing a loosened hair style, perhaps making it underrepresented in the clinic.

Trichotillomania is an impulse-control disorder where patients consciously or unconsciously pull, twist, or twirl their hair. It is a relatively common disorder in children. The mean age of onset is at about age 13 years, and it affects an estimated 4% of the population. Patients usually present with frontoparietal patches of alopecia that progress posteriorly and bare patches are typical. Trichoscopy shows broken hair shafts of various lengths typically with frayed "split ends." The condition is associated with problems of self-esteem and social avoidance. Complications include infection, skin damage, and scarring.[1,40]

The above and other causes of hair loss in children are listed in Table 120-8.

TABLE 120-8

Common Causes of Hair Loss in Children

Alopecia areata
Telogen effluvium
Traction alopecia
Diffuse hair loss with abnormal texture
Trichotillomania
Hair abnormalities with atopic eczema
Folliculitis decalvans

COMPLICATIONS

⑥ Like other medical conditions, alopecia can be distressing, affecting the quality of life and causing psychological problems.[41] Loss of normal scalp hair increases the risk of sunburn and injury. Moreover, studies have shown that hair loss can be associated with depression, low self-esteem, and feelings of unattractiveness. Some studies show that men with hair loss are perceived, based solely on appearance, to be not as attractive and successful as men without hair loss. This is further discussed below in the "Hair Stigma" section.

DIAGNOSIS

Diagnosis of alopecia usually can be made clinically: by a meticulous patient history plus skin and hair examination. In cases of less certainty, further workup may be warranted.

Regarding patient history, the essential points to obtain include time of onset, course of hair loss, past medical history (autoimmune disease, medications, procedures, or surgery), and family history of alopecia. In children, physical and mental development should also be obtained. Then, an extensive physical evaluation can be performed to assess whether the patient has hypotrichosis or alopecia, the type of alopecia, hair shaft anomalies, hair quality, and other conditions of the scalp, including erythema, edema, pustules, scaling, atrophy, or scarring.

For hair examination, the hair tug and pull test is clinically popular since it is quick and easy to use, and it can also be done at multiple locations on the scalp for a more thorough assessment. This test distinguishes between loss from follicles and loss due to hair shaft fragility. First, the patient's hairs are separated into a 4- to 6-mm diameter bundle (approximately 50-60 hairs). The tug portion of the test involves gentle holding of hairs between the thumb and index finger near their root, then tugging with the other hand on the same strand at its distal part. The tug test is positive if more than 10% of the hairs fracture, suggesting hair shaft fragility. The pull test involves holding a hair close to the root between the thumb and index finger, then use a slight force to pull the hair out, causing mild discomfort but not pain. In general, telogen hairs are more likely to be extracted than anagen hairs. Furthermore, microscopic observation of the hair root can help distinguish anagen hairs (long sheath shaped) and telogen hairs (club shaped).[42]

In the case of suspected fungal infection, the wood lamp examination is an efficient test. For the test to be accurate, the hairs should be free of all hair applications such as deodorants or moisturizers. After the surroundings are darkened, the wood lamp is turned on and held about 5 to 10 in. (~12-25 cm) away from the skin. Some common fluorescent colors are listed in Table 120-9.

TABLE 120-9

Common Colors Shown on Wood Lamp Examination

Conditions/Organisms	Fluorescent color
Pityriasis versicolor by *Malassezia*	Yellowish or orange
Malassezia folliculitis	Bluish-white
Tinea capitis by *Microsporum* species	Blue-green
Tinea capitis by *Trichophyton schoenleinii*	Dull blue

Bacterial or viral infection usually can be further diagnosed with swabs for stain or culture.

In suspected cases of iron deficiency, complete blood count, ferritin, total iron-binding capacity, and transferrin saturation should be tested. If a female patient presents with alopecia along with virilization, clinicians should order dehydroepiandrosterone (DHEA) sulfate and testosterone analysis. Other systemic conditions such as lupus or hypothyroidism/hyperthyroidism can be assessed using their specific laboratory findings.

Alopecia in general does not need a biopsy for diagnosis, but this is sometimes performed for research purposes. Hairs can be biopsied transversely and may show miniaturization, especially in cases of AGA or telogen effluvium.

Genetic Testing in Androgenetic Alopecia

As mentioned in the pathophysiology section, many genetic factors may contribute to alopecia. However, more research is still needed before clinicians can reach a consensus in the screening test for AGA. Therefore, no genetic testing is officially recommended.

TREATMENT

7 There are a myriad of distinct and diverse causes and types of alopecia as discussed above; thus, treatment or management strategies should be as cause-specific as possible. Identified causes should be treated and/or eliminated as soon as practically feasible. Cause-specific management/treatment strategies include several considerations—infections, chemotherapy, iron deficiency, other nutritional deficiencies, physiological or emotional trauma, trichotillomania, and autoimmune diseases.

Infectious causes should be treated with the appropriate anti-infective agent(s) and treatment regimen (whether systemic or topical therapy as appropriate). Tinea capitis, which commonly manifests as patchy alopecia and usually caused by a *Trichophyton* species, requires a systemic antifungal with oral terbinafine or itraconazole and not a topical agent (it does not penetrate hair follicles sufficiently). See Chapter 143, "Superficial Fungal Infections," for further discussion of the treatment of mycotic infections of the scalp.

Chemotherapy-induced alopecia is generally a reversible and temporary condition. However, for the patient undergoing chemotherapy, having their hair fall out—seeing clumps of hair on pillows and brushes and bald areas on their head—may be emotionally distressing. Cold caps and scalp cooling systems reduce the amount of chemotherapeutic agents reaching the hair follicles and have been shown to significantly reduce the amount of hair loss[43] without increasing the risk of scalp skin metastases.[44] Other nondrug strategies include wigs, scarves/hats or other head coverings, and counseling/psychological support. Limited studies of topical or systemic drug therapies for prevention and treatment (using alopecia treatments discussed below) have not been that promising especially in preventing hair loss,[24] and the risk for affecting chemotherapy efficacy or toxicity must be kept in mind, even with nutraceuticals.[24] Reassuring the patients that hair regrowth will happen may be comforting and letting them know that occasionally the hair grows back differently (eg, may be fuller or curlier) can provide a positive outlook.

Iron deficiency is a known and reversible cause of alopecia. In this case, appropriate treatment is iron replacement therapy followed by iron supplementation once iron stores are replenished. Iron-deficiency anemia is further discussed in Chapter 122, "Anemias."

Other *nutritional deficiencies* including specific trace element deficiencies should be corrected if found, as these may possibly play a role in alopecia. For example, there may be an association between copper deficiency and AGA; decreased copper level in the frontal zones of scalp hair and serum were found in both men and women with AGA when compared with their respective matched controls and the differences were statistically significant.[45] There may also be an association between defective copper metabolism and trichorrhexis nodosa, although there are many other possible causes, including hypothyroidism and Menkes disease.[1]

Any physiologic or emotional *trauma or stressors* that preceded the alopecia could be the inciting cause. If the traumatic events or stressors are still present and ongoing, management strategies to ameliorate them would be helpful (eg, mindfulness techniques, relaxation clinics, counseling, or psychotherapy).

Trichotillomania may be treated via nonpharmacologic and/or pharmacotherapy—the optimal treatment is unknown, and psychiatric referral may be indicated. Cognitive behavior therapy and selective serotonin reuptake inhibitors (SSRIs) may be effective, and using both together may be more effective than either treatment used alone. Olanzapine and clomipramine may also be effective.[46]

Alopecia that is thought to be associated with *autoimmune diseases* as discussed above (eg, SLE, hypothyroidism) sometimes improves with treatment of the specific autoimmune disorder. Antibodies (eg, thyroid-antimicrosomal antibodies) may be involved in the pilar follicles, as antifollicular antibodies have been reported in alopecia.[47]

Pattern Baldness: Androgenetic Alopecia

8 There are recent reviews[1,48,49] and evidence-based guidelines[50,51] on the treatment of AGA in women and in men. Treatments include topical minoxidil, oral 5α-reductase inhibitors (finasteride, dutasteride) for men, hormonal therapies for women, and miscellaneous therapies including nutritional supplements and laser light therapy, with variable efficacy.

Male Baldness

Topical Therapy: Minoxidil

Minoxidil (2% or 5%) topical solution is the most common treatment for male baldness. It can prevent the progression of baldness and improve hair density and thickness, with hair regrowth being more robust at the vertex than in the frontal area of the head.[52] Its exact mechanism of action on hair follicles remains unclear. However, the main benefits seen may be prolongation of the anagen phase and hair shaft diameter.[51]

The 5% concentration has been recommended for greater efficacy; a randomized controlled trial (RCT) comparing 5% versus 2% minoxidil in men aged 18 to 49 years found 45% higher hair counts in those given 5% versus those given 2%.[53] There is insufficient evidence to recommend the 5% foam over the 5% solution.[50] The response to treatment should be assessed at 6 months.[50] If successful, treatment needs to continue indefinitely as hair loss recurs when treatment is interrupted or discontinued.[1,50]

Side effects of minoxidil lotion include transient telogen hair shedding—an indication that minoxidil is stimulating telogen follicles to re-enter anagen[50]—this usually normalizes within a few weeks to months and therapy should be continued and not stopped.[50] Hypertrichosis is more common with the 5% concentration and may reflect incorrect application. To minimize drug contamination of the pillow and inadvertent contact with the face during sleep, patients should be advised to use the medication at least 2 hours before going to bed.[50] Irritant and contact dermatitis sometimes occur. Minoxidil is an antihypertensive agent when used systemically, and uncommon to rare side effects of topical administration are related to its systemic effects on blood pressure: dizziness, headache, hypotension, tachycardia, or chest pain.

Systemic Therapy: Finasteride, Dutasteride

The 5α-reductase enzyme converts testosterone to DHT, the main androgen causing AGA. There are two types of 5α-reductases in humans: type I is primarily found in liver, skin, and scalp; and type II is found in the prostate, genitourinary tract, and hair follicle.[50] 5α-Reductase inhibitors were originally marketed for treatment of benign prostatic hyperplasia (BPH), and their efficacy for AGA was an incidental finding based on a “side effect” of BPH treatment.

Finasteride is a selective type II 5α-reductase inhibitor that reduces scalp production of DHT. Multiple RCTs have shown significant increases in total hair counts and/or other hair growth benefits in men at 6 months,[54,55] 12 months,[56,57] and 24 months.[58] A dose-ranging study found benefits at all doses greater than 0.2 mg/day but no greater difference between 5 mg/day versus 1 mg/day.[54] Thus, the recommended dose for male pattern baldness is finasteride 1 mg/day (the dose for BPH is 5 mg/day). A 4-year study (2-year observation, 2-year finasteride) found that hair follicles that can still produce a thick hair fiber responded to finasteride 1 mg/day by reducing the hair cycle lag phase by 40% (thus initiating active growth more rapidly) and increasing the duration of the anagen phase by 23%.[58] However, miniaturized hair follicles (ie, those that were producing thinner hair, defined as <40 µm thick) did not respond to finasteride.[58] This may be useful in future for patient selection and may be an explanation for nonresponders. In 2019, a follow-up study by the same investigators assessing finasteride pharmacodynamics in responders found finasteride-dependency and a rebound effect when finasteride was discontinued: after 12 months off-treatment, viable drug-responsive hair follicles began to rapidly miniaturize; and by 30 months off-treatment, 94% had miniaturized, which worsened the alopecia.[59] The authors concluded that drug dependency and a rebound phenomenon are new findings for finasteride use in alopecia.[59]

Side effects of finasteride include orthostatic hypotension, dizziness, decreased libido, impotence, and ejaculatory disorder. Two recent systematic reviews identified growing concerns about sexual dysfunctions[8,60] and patient counseling should be provided prior to starting treatment.[8] Finasteride is extensively metabolized; monitoring parameters include liver function tests (LFTs) prior to starting therapy and repeated every 6 months.[61] Finasteride is teratogenic (risk category X), and crushed or broken tablets should not be touched by pregnant women or women seeking to become pregnant (including pharmacists, other health professionals, and caregivers), as exposure to the active ingredient can occur.

Dutasteride is a double inhibitor of both type I and type II 5α-reductase. It is only approved for BPH in men (and not for AGA) in the United States and Canada, although it is approved in other countries (eg, Korea) for AGA. RCTs have shown that dutasteride 0.5 mg/day has efficacy in 6 months without significant side effects[62] and that in comparison with finasteride 1 mg/day or placebo, it is significantly more efficacious.[55] Total hair counts (2.54 and 1.13 cm diameter [1 and 0.44 in. diameter]) and hair width but not terminal hair counts (2.54 cm diameter [1 in. diameter]) were significantly greater at 24 weeks with dutasteride compared with finasteride or placebo.[55] Incidences of sexual dysfunction and breast disorders were similar between dutasteride and finasteride but lower in the placebo group.

Also similar to finasteride, dutasteride is teratogenic (risk category X), and skin contact with the active ingredient (if tablet is broken or crushed) should be avoided. Tablets should be swallowed whole and not chewed or crushed. There is a potential association with high-grade prostate cancer, but the risk is low. Dutasteride is also extensively metabolized; its already-long half-life (5 weeks) increases with age. Its concentration/pharmacodynamic effects may be increased during concomitant therapy with strong CYP3A4 inhibitors.

The most concerning side effect for 5α-reductase inhibitors (finasteride, dutasteride) appears to be sexual dysfunction. A 2019 systematic review and meta-analysis of adverse sexual effects of finasteride or dutasteride as treatment for male AGA evaluated 15 RCTs (4,495 participants).[60] This study found an overall 1.57-fold risk of any adverse sexual effects associated with the use of either finasteride 1 mg/day or dutasteride 0.5 mg/day; when analyzed separately, finasteride had a 1.66-fold risk and dutasteride had an increased risk that was not statistically significant (RR 1.37, 95% CI 0.81-2.32).[60] But there were many fewer dutasteride RCTs, which may account for the wide confidence interval.

Miscellaneous Therapies

Many other cosmetic, pharmaceutical, nutraceutical, and food products are marketed as alternative therapies for alopecia. But most of these have little to no clinical evidence of efficacy, especially robust RCTs. However, health practitioners should be somewhat knowledgeable about alternative therapies, as patients may be using them and/or have questions—for instance, if they have heard of or are considering these options.[50]

Mesotherapy is the microinjection of medications, vitamins, or other substances into the mesoderm (the middle layer of skin). Medications have included dutasteride, minoxidil, or other active ingredients. An RCT comparing mesotherapy to topical 5% minoxidil found little difference in the two types of treatments, the only difference being a variation of hair shaft diameter at 1 month that was not present at 4 months (the end of the study).[63] The mesohair solution contained 56 ingredients, including 24 amino acids, 13 vitamins, 4 coenzymes, 4 nucleic acids, 5 minerals, and 2 reducing agents, and the active ingredients decapeptide 4, acetyl decapeptide, and copper tripeptide.[63] A study of mesotherapy using 1 mL of dutasteride 0.01% demonstrated significant improvement after 9 months, but only 6 patients (5 males, 1 female) participated in the trial.[64]

Low-level laser (light) therapy (LLLT) can stimulate hair growth by scalp vasodilatation, but the exact mechanism is unclear.[65] LLLT devices are available commercially for home or clinic use in the United States and Canada.[66]

Platelet-rich plasma (PRP) therapy involves intradermal injections of autologous PRP into the scalp. A 2017 systematic review found that 7 of 14 studies reported a significant increase in hair density, ranging from 12.3 to 45.9 hairs/cm^2 (80-300 hairs/in.^{2}) with variable hair thickness and hair loss results.[67] The beneficial effects seem to begin with the first treatment and peak after 3 to 5 treatments, then attenuates and treatments must be continued to maintain benefits. Side effects include local irritation and pain.[66,67]

PRP is concentrated autologous platelets in plasma, and contains more than 20 growth factors, including platelet-derived growth factors. In AGA, PRP is thought to induce stem cell differentiation, prolong dermal papilla cell survival, prolong the anagen phase, and other mechanisms.[68] PRP has been compared to topical minoxidil and at 6 months, the PRP group scored higher in both global photography and patient satisfaction with a hair growth questionnaire.[69]

Ketoconazole inhibits the DHT pathway, and ketoconazole shampoo has been considered for use in combination with oral finasteride.[70]

Prostaglandin F2 analogues latanoprost and bimatoprost topical therapy are being studied for use in AGA. Early results seem promising.[70]

Topical valproic acid 8.3% spray was found to increase hair count in a recent RCT.[71] Alopecia is a fairly common adverse effect of systemic valproic acid.

Hair restoration surgery involves hair transplantation, scalp reduction surgery, or a combination of both.

Natural health products—including biotin, melatonin, saw palmetto, black cohosh, dong quai, false unicorn, chaste berry, and red clover—have been used in treatment of alopecia. Some of these may have anti-androgenic or estrogen-promoting activities.[65] However, there is scant evidence of efficacy as hair growth promoters in men, as shown in these summaries:

1. A small 2017 RCT of a combination traditional Chinese medicine (TCM) containing six herbal ingredients (*Ginseng Radix*, *Astragali Radix*, *Angelicae Sinensis Radix*, *Ligustri Fructus*, *Rehmannia glutinosa*, and *Eclipta prostrata* Linn.) versus placebo showed that 9 of 17 patients receiving TCM had increased hair growth versus 2 of 17 in the placebo group, a statistically significant difference. However, of the 9 responders in the TCM group, 1 minimally improved, 5 moderately improved, and only 3 showed significant improvement.[72]
2. Biotin is popularly used for AGA; although it is known that genetic biotinidase deficiency results in hair loss and biotin was found to reverse valproic acid–induced alopecia in a few patients, robust evidence is lacking.[73]
3. In contrast, a well-designed 2017 RCT of a commercially available product called Lambdapil (1,000 mg L-Cysteine, 100 mg *Serenoa repens*, 7.14 mg *Equisetum arvense L*, 0.5 mg silicon, 10 mg zinc, 16 mg vitamin B3, 6 mg vitamin B5, 1.4 mg vitamin B6, 50 µg D-biotin, 40 mg taurine), which enrolled both men and women in a 6 month placebo-controlled RCT using high-level methodology, found that Lambdapil increased the anagen/telogen ratio in men, with a 3.7% increase in anagen hair and an increase in hair volume. Quality of life was also improved.[74] (Results of the use of this product in women are discussed in the next section.)

Female Hair Loss

The majority of female hair loss is FPHL or female pattern AGA; however, women with PCOS also can develop male pattern baldness. A 2016 Cochrane review of interventions for FPHL reported moderate- to low-quality evidence of efficacy for minoxidil, low-quality evidence of efficacy for finasteride, and moderate- to low-quality evidence of efficacy for.[49] Hormonal therapy, nutraceuticals, and mesotherapy were not included in the review, although there are promising RCTs of these approaches. Other possibilities such as prostaglandin analogs are too early in development for review. Recently published management strategies include other hormone-modulating treatments (dutasteride, spironolactone, cyproterone acetate, flutamide), ketoconazole shampoo, platelet-rich plasma, microneedling, as well as updated comments on prostaglandin analogues (latanoprost, bimatoprost), light therapy, topical hormonal treatments, and hair transplant.[75]

Topical *minoxidil* 2% has been approved for use in females with AGA, but not the 5% concentration. Many RCTs using 2% minoxidil in women have shown efficacy, and pooled data from six studies (5 using 2%, 1 using 1%) confirmed the observation, with 157 of 593 patients demonstrating a moderate-to-marked increase in hair growth when compared with placebo (RR 1.93, 95% CI 1.51-2.47).[49] In 8 pooled studies (1,242 participants), there was a significant increase in total hair count (13.2/cm^2 [85/in.^{2}]) compared with placebo.[49] Four studies (1,006 participants) comparing minoxidil 2% versus 5% did not show a difference, although the quality of the evidence was moderate to low.[49] If successful, it should be continued indefinitely.[75] Women should be informed about transient telogen hair loss within the first few months of treatment and possible hypertrichosis as a side effect of treatment.[75] Minoxidil, including topical use, is contraindicated in pregnancy and lactation.

Oral *minoxidil* at low doses of 0.25 to 2.5 mg/day may be an option if unresponsive or intolerant to topical minoxidil treatment.[75] However, significant drops in blood pressure may occur, especially if other anti-hypertensive medications are used concomitantly.

Topical and oral prostaglandin analog treatments may be promising. Latanoprost, travoprost, and bimatoprost are prostaglandin analogs that are used for glaucoma, which caused eyelashes to grow as a side effect; they promote hair growth by prolonging the anagen phase. Blocking the prostaglandin D2 receptor (GPR44) may help to increase hair growth.[75] Setipiprant (KITH-105) is an oral GPR44 receptor inhibitor. Studies are ongoing but still too early to provide general guidance.

5α-Reductase inhibitors are not approved for use in females. One RCT showed efficacy with *finasteride* 1 mg/day in women with AGA while two others did not.[49] Higher doses (2.5-5 mg/day) have shown efficacy consistently[75-78] and are used in practice.[75] Patient selection and dose used may be key—at 1 mg/day four women with hyperandrogenism showed improvement with finasteride[79] but not postmenopausal women without hyperandrogenism.[48,80] However, at a dose of 5 mg/day, 86 mostly postmenopausal Asian women without hyperandrogenism showed significant increases in mean hair density and mean hair thickness after 12 months of treatment.[77] Studies in premenopausal women have shown conflicting results.[80] *Dutasteride* is a more potent 5α-reductase inhibitor that can lower serum DHT levels by more than 90%[80] and effectiveness has been reported in a 46-year-old woman.[81] Precautions and concerns with handling broken tablets are even more of an issue if used by a woman, as the drug is contraindicated in pregnancy and in women of childbearing age.

Hormonal therapy with antiandrogens with or without estrogens has shown some efficacy. In particular, *cyproterone acetate* was compared with topical minoxidil; results showed greater efficacy for minoxidil in women without hyperandrogenism and greater efficacy for cyproterone acetate in women with multiple symptoms of hyperandrogenism.[82] Cyproterone acetate may be more effective in a birth control formulation (eg, Diane or Diane-35, which is available in Canada and Europe but not in the United States). Suggested regimens for use in premenstrual women are either 100 mg/day on days 5 to 15 alongside ethinyl estradiol 50 µg on days 5 to 25, or 50 mg/day on days 1 to 10 with ethinyl estradiol 35 µg on days 1 to 21.[75] For postmenopausal women, a suggested regimen is cyproterone acetate 50 mg/day.[75]

Spironolactone has antiandrogenic activities and has been considered the most commonly used, off-label antiandrogen for the treatment of FPHL and hirsutism[48]; however, published studies are limited. An open intervention study found spironolactone to be equally effective when compared with cyproterone acetate.[83]

Flutamide has potent antiandrogenic effects and has shown efficacy for FPHL in clinical trials. In a 4-year prospective cohort study in which flutamide was used in annually reduced doses of 250 mg/day, 125 mg/day, and 62.5 mg/day, flutamide was used either alone or with an oral contraceptive reduced alopecia scores. The maximum drug effect occurred after 2 years and was maintained for the duration of the 4-year study.[84] The regimen of annually reduced doses was a dose-ranging attempt to minimize side effects; the study showed that the dose of 62.5 mg/day maintained efficacy with complete hepatic tolerability and high adherence. At the dose of 250 mg/day, the dropout rate was 4% due to drug-related hepatic changes.[84] Monitor serum transaminases at baseline, monthly for the first 4 months and periodically thereafter.[75,85]

Natural health products and nutritional supplements may be beneficial. RCTs showing efficacy are as follows[81]:

1. A 2015 RCT of a nutritional supplement combination (460-mg fish oil [exact amounts of EPA and DHA unspecified], 460-mg black currant seed oil, antioxidants [1-mg lycopene, 30-mg vitamin C, 5-mg vitamin E])[86,87] versus placebo in 120 women found that 62% of the supplement group had increased hair density compared with 28% in the placebo group. Anagen hair increased significantly and telogen hair decreased significantly in the supplement group.[86,87]
2. The well-designed 2017 RCT of Lambdapil as discussed in an earlier section enrolled both women with acute Telogen effluvium (aTE) and men with AGA in a 6-month, placebo-controlled design using high-level methodology. Results in women showed an increase in hair volume (slight to moderate) and an improved quality of life.[74]
3. A topical botanical lotion that acts by increasing Bcl-2, perifollicular Langerhans and mast cells, and perifollicular collagen was found in a 2018 single-blinded RCT to increase hair density, improve Dermatology Life Quality Index, and increase the anagen:telogen ratio at 24 weeks.[88]

LLLT increased the total hair count in women with FPHL in several studies.[49,89] A 2019 meta-analysis of 8 papers comprising a total of 11 RCTs found that LLLT device used (comb vs helmet) and the duration of treatment (short vs long) did not appear to matter. Thus, LLLT appears promising and is a potentially effective treatment for AGA.[89] Majority of studies to date have shown an overall improvement in hair regrowth, thickness, and patient satisfaction.[75] To this end, the FDA has approved various LLLT devices for use in AGA and these are available commercially. LLLT is usually well tolerated, with side effects that include scalp dryness, itching, tenderness, and a warm sensation.[75]

Platelet-Rich Plasma may be a promising option for female AGA[75,90]; however, current European Guidelines for AGA in women and men concluded that there is insufficient evidence to support its use.[75,91]

Mesotherapy containing nutritional supplements has been compared with topical minoxidil 5% lotion. No significant differences were found with regard to hair density or hair loss, but the mesotherapy group had a greater increase in the number of hair follicles.[92]

Hair transplantation is a viable option if other medical therapies are unsuccessful.[75] Cosmetic methods such as wigs, scarves, and hats are other alternatives.

Ketoconazole shampoo has been recommended for female AGA if seborrheic dermatitis or sebopsoriasis is present.[75]

Androgenetic Alopecia in Children

Familial predisposition may be present. Nonetheless, if AGA is seen in a prepubertal child, an endocrine evaluation is strongly recommended.[93] AGA in an adolescent is not uncommon and topical minoxidil may be effectively used.[42,94] One case report of AGA seen in a 15-year-old girl was successfully treated with topical minoxidil and oral contraceptives.[95]

Alopecia Areata

Alopecia areata (AA) can be emotionally devastating to a person and can cause a significant impact on the patient's quality of life and self-esteem.[4] It can cause stigmatization[34] (see the "Hair Stigma and Hair Discordance" section). It may lead to clinical depression, anxiety, and/or social phobia. Management and treatment of the psychological impact of AA must not be overlooked.

9 Curative therapy for AA does not yet exist; however, there is a high rate of spontaneous remission even with no pharmacotherapy.[4] Alopecia totalis and alopecia universalis are more resistant to treatment. Due to the autoimmune and inflammatory nature of AA, effective pharmacotherapy primarily involves immunosuppressive agents used systemically, intralesionally, and/or topically. Treatments that may be effective include high-dose oral corticosteroids, intralesional corticosteroids, topical corticosteroids, topical minoxidil, topical immunotherapy, systemic and topical biologic agents (in particular the Janus kinase inhibitors discussed later in this section), azathioprine and other immunosuppressive agents, and a few miscellaneous agents. Robust RCTs are lacking or limited for some of these therapies; some treatments may not be suitable for children with AA.

Intralesional corticosteroids are the treatment of choice in adults.[34] The best-tested immunosuppressive treatment is intradermal (intralesional) triamcinolone acetonide (5-10 mg/mL) every 2 weeks[4] or every 4 to 6 weeks.[34] Monthly intervals would be more convenient for the patient. An effective method is to inject 0.1 mL of solution into multiple sites at 1 cm (0.4 in.) apart, into the deep dermis, with a maximum volume of 20 mL injected at each clinic visit.[34] This treatment stimulates regrowth in more than 60% of patients.[4] If there is no improvement at 6 months or if significant atrophy is noted, treatment should be discontinued.

Hydrocortisone acetate (25 mg/mL) is an alternative. Side effects include pain at injection sites, localized skin atrophy, and hypopigmentation. Dermal atrophy usually recovers over 3 to 6 months.[34] Relapses are common with treatment discontinuation.[4]

Topical corticosteroids (TCS) are commonly used, especially in children (since scalp injections are painful) and in those adults with less than 50% scalp involvement.[4] High-potency TCS such as clobetasol propionate used under occlusion is more effective since this may further increase potency. (As an aside, although keloid is an entirely different disease entity, a recent RCT found that clobetasol propionate 0.05% cream under silicone occlusion dressing was equally efficacious and had fewer adverse effects compared with intralesional triamcinolone.[96]) Treatment for AA may need to be continued for 3 months before regrowth is seen.[34] Monitor for topical and potentially systemic side effects since potent TCS are being used.[97] Folliculitis is a common side effect. Refer to Chapter 118, "Psoriasis/Psoriatic Arthrtis," for a corticosteroid potency comparison chart and for a detailed discussion of TCS side effects. A recent article about rational and ethical use of TCS also provides a summary.[97]

Systemic corticosteroids are efficacious in patients with AA. However, their side effects profile limits their use to short treatment periods of 2 to 3 months. Pulse dosing (eg, once weekly) is used to minimize systemic side effects. Regimens include prednisolone 0.5 mg/kg/day (usually of 40-50 mg/day) daily for 3 months,[34] prednisolone 200 mg once weekly for 3 months,[4] or dexamethasone 0.1 mg/kg/day (mean dose about 8 mg) on 2 consecutive days once weekly for at least 4 months and then slowly tapered or discontinued (with some patients on treatment for 2 years).[98] This dexamethasone regimen was used in 31 patients with alopecia totalis or alopecia universalis, and complete response was seen in 22 patients (71%) and partial response in 3 patients (10%). The mean time to response was 1.55 months, and the mean duration of therapy was 12.9 months (range 4-24 months). Adverse effects were seen in 10 of 31 patients (32%), including weight gain in 9 patients and Cushing syndrome, striae, and irritability in 1 patient each.

Relapses are seen after treatment is discontinued and sometimes during treatment.[98] Pulse therapy with high-dose systemic steroids has been used in other studies and may be an option for severe, extensive, or recalcitrant AA.

Biologic agents have exploded on the treatment scene for many dermatologic inflammatory disorders such as psoriasis, atopic dermatitis (AD), and AA, including the subtypes alopecia totalis (AT) and alopecia universalis (AU). Some biologic agents may be used topically for AA, and some have been successfully used in children and adolescents.

Janus kinase (JAK) inhibitors (tofacitinib, ruxolitinib, baricitinib) are a promising new class of biologic treatment for AA.[99,100] A JAK-STAT (signal transducer and activator of transcription) signaling pathway is important in the hair growth cycle, with key genes being highly expressed in the catagen and telogen phases but suppressed in the anagen phase.[99] JAK inhibitors inhibit the JAK-STAT pathway, resulting in various immunologic changes that result in prolonging the anagen phase, angiogenesis, stimulating/activating the proliferation of hair stem cells, and other changes, which all manifest in hair regrowth, as shown in these studies[99]:

1. Studies and case reports of oral and topical *tofacitinib* demonstrate efficacy in adults and children with AA, including AA subtypes AT and AU.[100] Patients with AA may have greater response than patients with AA subtypes. Systemic treatments may be more effective than the topical route. Using the Severity of Alopecia Tool (SALT), a cohort study of oral tofacitinib 5 to 10 mg twice daily in 90 adults with AA and subtypes, found that 58% improved their SALT score by 50% or more over 4 to 18 months of treatment. Patients with AA showed a greater degree of change in SALT than those with alopecia totalis or universalis (82% vs 59%).[100] A retrospective review of 13 adolescents with AA treated with tofacitinib 5 mg twice daily found a 90% median improvement in SALT score (1%-100%), and there are many other recent studies.[100] A retrospective review of children under 12 years with AA, AT, or AU treated with tofacitinib identified three children aged 5 years or younger who failed previous treatment before tofacitinib and who responded to tofacitinib 2.5 mg daily for 4 days then 5 mg daily for 3 days each week (one child with >90% hair regrowth after 12 months of treatment and the other two children with >50% improvement by 6 months and 21 months, respectively).[101] Results with topical JAK inhibitors are poorer than with oral agents. Topical tofacitinib or ruxolitinib were applied to eyebrow regions/upper eyelids/scalp in 6 pediatric patients aged 3 to 17 years with AA, and responses were only seen in 3 patients.[102] Additional clinical studies are under way.
2. Fewer reports and studies have examined the use of *ruxolitinib;* however, there are reports of efficacy in hair regrowth in a few patients with AT who had failed therapy with tofacitinib.[103] Encouraging results and additional studies are under way.
3. There is one case report of oral *baricitinib* being effective in AA as an incidental finding, and other JAK inhibitors are on the horizon, including filgotinib and decernotinib, which are being tested for rheumatoid arthritis.

Dupilumab is a new class of biologic agents (an IL-4 receptor-α-antagonist) marketed for AD. It was found to trigger hair regrowth in two case reports of AD patients using dupilumab for AD: one case was a patient with long-standing AT[104] and the other case was a patient with long-standing AU.[105]

Methotrexate is a systemic immunosuppressive agent which may be an option for AA with extensive hair loss where other treatments have been ineffective. If efficacious, regrowth may be seen in 3 months with full regrowth in 6 to 12 months. Methotrexate is more efficacious when used with prednisone or prednisolone (various regimens). A regimen starting with IV methylprednisolone (500 mg/d × 3 days, then monthly × 3 cycles) prior to starting oral methotrexate has also shown efficacy in several studies.[106] Various dosing regimens of methotrexate have been used, most with starting doses of 2.5-10 mg/week and increasing to 15-25 mg/week.[106] In adults and children with severe AA, response to methotrexate was better in adults than in children, confirming that combination treatment with a corticosteroid results in higher complete response rates than methotrexate used alone.[106] Tapering often resulted in recurrence.[106]

Azathioprine has also been successfully used to treat AU including recalcitrant cases in adults (nonresponders to oral corticosteroids and topical immunotherapy with diphencyprone). A case study of 14 adult patients showed a complete response in 6 of 14 patients (43%). No identifiable prognostic factors were found, and adverse effects included elevated liver enzymes (1 patient), pancreatitis (1 patient), bone marrow suppression (1 patient), and diarrhea (2 patients); treatment had to be discontinued in 4 patients.[107]

Other agents have been tried for treating AA over the years with varying levels of success, including topical anthralin,[108,109] topical diphenylcyclopropenone,[109] topical calcineurin inhibitors, and oral cyclosporine. None of these is commonly used today because of inconsistent efficacy and/or side effects.

Loss of Eyelashes and Eyebrows

Bimatoprost (Latisse) 0.03% drops is FDA approved for treatment of hypotrichosis of the eyelashes, discovered due to increased eyelash growth observed through usual use for elevated intraocular pressure in glaucoma. One drop is applied along the skin of the upper eyelid at the base of eyelashes once daily at bedtime. Beneficial effects may take months to be seen.[110,111] Bimatoprost 0.03% solution has also shown efficacy in hypotrichosis of the eyebrows.[112]

HAIR CARE IN THE PATIENT WITH ALOPECIA

Patients suffering from alopecia may attempt to manipulate their hair to hide their hair loss and to make their head of hair appear fuller; however, most methods may actually further damage the hair and are not recommended. Chemical processing such as hair weaving or hair straightening can further damage the hair and cause hair breakage.

All hair dyes can damage the hair with the exception of temporary hair dyes. Temporary hair dyes have particle sizes that are too large to penetrate through the cuticle, which minimizes hair damage and accounts for their temporary nature (they are removed by a single shampooing).

Heat denatures the keratin protein structure of the hair shaft and turns the water in the hair shaft into steam. This can physically remove the cuticular scale as the steam escapes from the hair shaft. Without the structural protection afforded by the cuticular scale, the hair breaks easily. Heat-damaged hair is known as bubble hair and cannot be repaired. Frequent hair combing or brushing may also damage the hair by encouraging cuticle removal.[113]

Hair should be combed or brushed only when dry, and excessive combing or brushing should be avoided. Brushing the hair 100 strokes a day and massaging the scalp vigorously with the brush are not appropriate for the patient with alopecia.[113]

Hair conditioners coat the hair shaft and smooth the cuticle, and they should be routinely used. Instant conditioners that are applied after shampooing and rinsed out coat the hair shaft with a thin dimethicone or quaternary ammonium compound to temporarily “glue down” loosened cuticular scales. Supplementing these with a leave-in conditioner can provide a thicker coating to further protect the hair until the next shampoo. Hair conditioners reduce combing friction, improve hair shine, increase hair softness, minimize static electricity, and reduce frizziness.[113]

HAIR STIGMA AND HAIR DISCORDANCE

“Beauty standards of hair are a form of bias.”[114] Men, women, adolescents, and children are often distressed when there is hair loss, or when their hair is perceived as “different” from the societal norm—such as in minoritized people of color. Adolescents and children in particular may be subject to bullying by their peers, sometimes just for having a head of hair that looks different.[115] In 2019, an anti-bullying song/video was released and a cosmetic manufacturer partnered in an anti-bullying campaign.[114,115]

Imagine the potential stigmatization/bullying situation if the person had patchy AA or AA totalis? This is involuntary hair loss which is quite different from people who have chosen to shave their heads such as monks. Stigmatization affects adults as well. Healthcare professionals should be cognizant of the psychosocial impact on their patient’s quality of life. A 2015 review of the burden of disease for patients with AA reported rates for depression (8.8%) and generalized anxiety disorder (18.2%), both significantly higher than in the general population (about 1%-2%).[41] This review also found that the rate of psychiatric comorbidity was influenced by the age of onset of AA, with an increased risk of depression in patients aged <20 years and increased risks of anxiety and obsessive-compulsive disorder in patients aged 40 to 59 years.[41]

Similarly, in patients with AGA or other forms of alopecia, the psychosocial impact must not be overlooked. Even with temporary anagen hair loss (such as chemotherapy-induced alopecia), the onset is usually sudden and may be absolutely traumatizing to the patient.

In addition, hair discordance may be present between a healthcare professional and an alopecia patient of color seeking care. There may be patient discomfort and/or a negative perception of the ability of the healthcare professional to meet their care needs. A survey of Black women with alopecia reported that some physicians did not touch their hair, and some were unfamiliar with their usual hair care routine.[116] Another recent study noted that alopecia is one of the most common conditions for patients of African descent being seen by a dermatologist.[117]

Thus, healthcare professionals should be cognizant that hair stigma and hair discordance may be potential issues. Being aware of common cultural hair care practices and being empathetic in interactions with the patient with alopecia are important components of care.

An approach to examining tightly coiled hair for patients with hair loss in race-discordant patient-physician interactions is available, describing appropriate actions, tips for hair examination, and sample language appropriate for the interaction.[118]

CONCLUSION

Alopecia is the visible result of many diverse causes, some of which may be temporary and easily reversible and others refractory to therapy. Identifying the cause is key. Management/treatment of alopecia should be as cause-specific as possible. In addition, psychosocial support should always be considered.

ABBREVIATIONS

ACTH	adrenocorticotropic hormone
AA	alopecia areata
AD	atopic dermatitis
AGA	androgenetic alopecia
AT	alopecia totalis (or alopecia areata totalis)
aTE	acute telogen effluvium
AU	alopecia universalis (or alopecia areata universalis)
BMPs	bone morphogenetic proteins
BPH	benign prostatic hyperplasia
CI	confidence interval
DHEA	dehydroepiandrosterone
DHT	dihydrotestosterone
F	female
FGF	fibroblast growth factor
FPHL	female pattern hair loss
HGF	hepatic growth factor
IGF	insulin-like growth factor
IL	interleukin
JAK-STAT	Janus Kinase-signal transducer and activator of transcription
KOH	potassium hydroxide

LFTs	liver function tests
LLLL	low-level laser light
M	male
NT	neurotrophins
PCOS	polycystic ovarian syndrome
PRP	platelet-rich plasma
QoL	quality of life
RCT	randomized controlled trial
RR	risk ratio
SALT	severity of Alopecia Tool
SLE	systemic lupus erythematosus
SSRI	selective serotonin reuptake inhibitor
TCM	traditional Chinese medicine
TCS	topical corticosteroids
TGF	transforming growth factor
TNF	tumor necrosis factor
WNT	aportmanteau created from the name Wingless and the name Int-1
VEGF	vascular endothelial growth factor

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements about the hair shaft is incorrect?

   A. The cuticle is responsible for elasticity and resiliency.

   B. The cortex contains melanin and determines hair color.

   C. The medulla contains keratin and determines whether the hair is straight or curly.

   D. There are three layers of the hair shaft namely the cuticle, the cortex, and the medulla.

2. The infundibulum is:

   A. A reservoir for the sebaceous gland

   B. A funnel shaped cavity

   C. Usually filled with sebum

   D. In the lower segment of the hair follicle

3. The phases of the hair cycle, beginning with the growth phase, are:

   A. Anagen, Telogen, Catagen, Exogen

   B. Anagen, Catagen, Telogen, Exogen

   C. Catagen, Telogen, Exogen, Anagen

   D. Anagen, Catagen, Telogen, Exogen

4. Which of the following growth factors is not part of the anagen phase?

   A. Transforming growth factor β1 (TGF-β1)

   B. Insulin-like growth factor-1 (IGF-1)

   C. Fibroblast growth factor-7 (FGF-7)

   D. Hepatic growth factor (HGF)

5. The hormone most responsible for pattern hair loss is:

   A. Testosterone

   B. Adrenocorticotropic hormone

   C. Dihydrotestosterone (DHT)

   D. Thyroid hormone

6. The most common cause of inflammation-induced alopecia is:

   A. Alopecia areata

   B. Androgenetic alopecia

   C. Psoriatic alopecia

   D. Isotretinoin

7. Tinea capitis presents with all of the following EXCEPT:

   A. Scaling

   B. Patchy hair loss

   C. Black dots

   D. Honey-colored crusts

8. Scarring hair loss may be caused by:

   A. Frontal fibrosing alopecia

   B. Chronic cutaneous lupus erythematosus

   C. Burns

   D. All of the above

9. “Exclamation mark” hairs are associated with:

   A. Androgenetic alopecia

   B. Alopecia areata

   C. Cicatricial alopecia

   D. Allergic contact dermatitis of the scalp

10. Treatment of trichotillomania includes all of the following EXCEPT:
    A. Cognitive behavior therapy
    B. Selective serotonin reuptake inhibitors
    C. Mesotherapy
    D. Olanzapine
11. Which of the following statements is true about topical minoxidil?
    A. It is a treatment for alopecia areata.
    B. The 5% lotion is recommended for use in women with alopecia.
    C. Hair shedding/hair loss may occur for a few weeks to months when it is first used.
    D. Topical use avoids systemic side effects totally.
12. Which of the following statements is true about finasteride?
    A. It reduces scalp production of DHT.
    B. It can increase total hair counts after 6 months of use.
    C. Miniaturized hair follicles do not respond to finasteride.
    D. All of the above are true statements.
13. The most concerning side effect for finasteride and dutasteride is:
    A. Nephrotoxicity
    B. Sexual dysfunction
    C. GI intolerance
    D. Muscle cramps
14. The treatment of choice for alopecia areata in adults is:
    A. Intralesional corticosteroids such as triamcinolone acetonide
    B. Systemic corticosteroids such as prednisone
    C. Dupilumab
    D. Azathioprine
15. Appropriate hair care for patients with alopecia include all of the following EXCEPT:
    A. Hair conditioners after each shampoo
    B. Supplementing with a leave-in hair conditioner
    C. Combing/brushing hair only when dry
    D. Brushing the hair 100 strokes a day

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** It's the cortex that contains keratin and determines whether the hair is straight or curly.
2. **D.** It is in the upper segment of the hair follicle.
3. **D.** Response D shows the correct order of the hair cycle, beginning with the growth phase.
4. **A.** The transforming growth factor is part of the catagen phase.
5. **C.** DHT has greater affinity to androgen receptors than testosterone and is responsible for shortening the telogen phase, leading to more rapid hair loss.
6. **A.** Alopecia areata is the most common cause of inflammation-induced alopecia, although inflammation also plays a role in androgenetic alopecia and psoriatic alopecia.
7. **D.** Honey-colored crusts are associated with seborrheic dermatitis.
8. **D.** All are potentials causes of scarring hair loss.
9. **B.** "Exclamation mark" hairs are hairs where the distal hair shaft is broader than the proximal end, and this is associated with alopecia areata.
10. **C.** Mesotherapy is a treatment possibly useful for androgenetic alopecia.
11. **C.** Transient hair loss may initially occur, which indicates that minoxidil is stimulating telogen follicles to re-enter anagen.
12. **D.** All of the listed statements are correct with regard to finasteride.
13. **B.** Sexual dysfunction is the most concerning adverse effect of these agents.
14. **A.** Although benefits have been shown for B, C, and D, these are not the treatment of choice. Systemic corticosteroids should only be used for short treatment periods of 23 months due to their side-effects profile. Dupilumab is marketed for atopic dermatitis, and benefits in alopecia areata has been an incidental finding. Azathioprine may be an alternative treatment in recalcitrant cases in adults.
15. **D.** It is inappropriate to brush the hair 100 strokes a day or massage the scalp vigorously with the hair brush.

Chapter 122: Anemias

KEY CONCEPTS

KEY CONCEPTS

① Anemia is a group of diseases characterized by a decrease in either hemoglobin (Hb) or the volume of red blood cells (RBCs), which results in decreased oxygen-carrying capacity of the blood. Anemia is defined by the World Health Organization (WHO) as Hb less than 13 g/dL (130 g/L; 8.07 mmol/L) in men and less than 12 g/dL (120 g/L; 7.45 mmol/L) in women.

② Acute-onset anemias are most likely to present with tachycardia, lightheadedness, and dyspnea. Chronic anemia often presents with weakness, fatigue, headache, vertigo, and pallor.

③ Iron-deficiency anemia (IDA) is characterized by decreased ferritin levels (most sensitive marker) and serum iron, and decreased transferrin saturation. Hb and hematocrit decrease later. RBC morphology includes hypochromia and microcytosis. Most patients are adequately treated with oral iron therapy, although parenteral iron therapy is necessary in some patients.

④ Vitamin B_{12} deficiency, a macrocytic anemia, can be due to inadequate intake, malabsorption syndromes, and inadequate utilization. Anemia caused by lack of intrinsic factor, resulting in decreased vitamin B_{12} absorption, is called *pernicious anemia*. Neurologic symptoms can be present and can become irreversible if the vitamin B_{12} deficiency is not treated promptly. Oral or parenteral therapy can be used for replacement.

⑤ Folic acid deficiency, a macrocytic anemia, results from inadequate intake, decreased absorption, and increased folate requirements. Treatment consists of oral administration of folic acid, even for patients with absorption problems. Adequate folic acid intake is essential in women of childbearing age to decrease the risk of neural tube defects in their children.

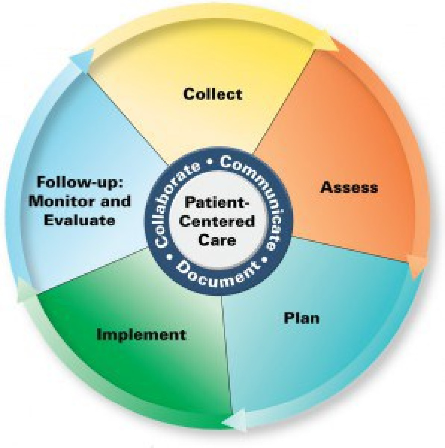
⑥ Anemia of inflammation (AI) is a newer term used to describe both anemia of chronic disease and anemia of critical illness. AI is a diagnosis of exclusion. It results from chronic inflammation, infection, or malignancy and can occur as early as 1 to 2 months after the onset of the disease. The serum iron level is usually decreased, but in contrast to IDA, the serum ferritin concentration is normal or increased. Treatment is aimed at correcting the underlying pathology. Anemia of critical illness occurs within days of acute illness.

⑦ Anemia is a common problem in older adults, although not an inevitable complication of aging. Low Hb concentrations are not “normal” in older adults. Anemia is associated with an increased risk of hospitalization and mortality, reduced quality of life, and decreased physical functioning in older adults.

⑧ IDA is a leading cause of infant morbidity and mortality worldwide. Age- and sex-adjusted norms must be used to interpret laboratory results for pediatric patients. Primary prevention of IDA is the goal because physical and mental developmental delays can be irreversible.

PATIENT CARE PROCESS

Patient Care Process for Anemia



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

The image shows the five fundamental steps included in The Pharmacist's Care Process endorsed by the Joint Commission for Pharmacy Practitioners (2014). The tagline of this process reads collaborate, communicate, and document. The five fundamental steps listed here are collect, assess, plan, implement, and follow-up: monitor and evaluate. All these steps are listed in a circular block diagram.

Collect

- Patient characteristics (eg, age, race, sex, pregnancy)
- Patient history (eg, past medical history, dietary habits, physical activity, alcohol intake, smoking status, chemical exposure)
- Symptoms of anemia (eg, fatigue, weakness, chest pain, dizziness, pallor, see "Clinical Presentation: Anemia" box)
- Current medications (including over-the-counter and supplements)
- Objective data (see "Clinical Presentation: Anemia" box)
    - Blood pressure (BP), heart rate (HR)
    - Labs (CBC, iron studies, vitamin B_{12}, folate, homocysteine, MMA, etc.)

Assess

- Underlying disease states (blood loss, heart failure, chronic renal disease, HIV, malignancy; see Table 122-1)
- Dietary habits and potential social factors contributing to nutritional deficiencies
- Acuity of symptoms and need for transfusion or hospitalization
- Current medications that may contribute to or worsen anemia or blood loss
- Lab results to determine underlying etiology of anemia for proper treatment selection or attainment of treatment goals
- Ability to self-inject medications (eg, cyanocobalamin)

Plan*

- Dietary interventions for nutritional deficiencies
- Initiate appropriate drug therapy treatment based on etiology (correct formulation, strength, dosing, frequency, and address pertinent drug interactions [see Table 122-3 for iron product selection/drug interactions])

- Monitoring for efficacy and safety (labs and symptom improvement, corrected etiology if possible, adverse drug reactions)
- Patient education (expectations/purpose of treatment, adverse effects, diet modifications, etc.)
- Improved treatment of underlying pathologies if contributing to anemia of chronic disease

Implement*

- Educate patient on treatment interventions and treatment expectations
- Reinforce adherence to treatment plan for short- and long-term success
- Schedule patient for follow-up at appropriate intervals

Follow-up: Monitor and Evaluate

- Lab values within 4 weeks after treatment initiation
- Tolerability of medications
- Symptom improvement (eg, fatigue, pallor, weakness, dizziness, neuropathy)
- If minimal improvement or worsening, determine whether etiology of anemia was correct

******Collaborate with patient, caregivers, and other healthcare professionals.*

Write a paragraph that explains the pathophysiology of anemia to a patient. You can only use patient friendly language.

INTRODUCTION

Anemia affects almost one third of the world's population, with developing countries carrying the highest burden.[1] Anemia is defined by the WHO as hemoglobin (Hb) less than 13 g/dL (130 g/L; 8.07 mmol/L) in men or less than 12 g/dL (120 g/L; 7.45 mmol/L) in women.[2] In the United States, about 3 million people have anemia.[3] Millions of people are unaware they have anemia, making it one of the most underdiagnosed conditions in the United States. Iron deficiency is the leading cause of anemia worldwide, accounting for as many as 50% of cases.[2] Although nutritional deficiencies occur less often in the United States, they can occur in at risk populations (discussed in more detail later). Anemia is not an innocent bystander because it can affect both length and quality of life. Retrospective observational studies of hemodialysis patients and heart failure patients suggest that anemia is an independent risk factor for mortality.[4] In addition, anemia significantly influences morbidity in patients with end-stage renal disease, chronic kidney disease, and heart failure.[5] Anemia is associated with psychomotor and cognitive abnormalities in children. Similarly, anemia is associated with cognitive dysfunction in patients with renal failure or cancer, and among community-dwelling elders.[6] Anemia during pregnancy is associated with increased risk for low birth weights, preterm delivery, and perinatal mortality.[7] Maternal IDA may be associated with postpartum depression in mothers and poor performance by offspring on mental and psychomotor tests. In older adults, anemia is associated with a greater risk for falls and dementia.[8] Global goals of treatment in anemic patients are to alleviate signs and symptoms, correct the underlying etiology, and prevent recurrence of anemia.

① Anemia is a group of diseases characterized by a decrease in Hb or circulating red blood cells (RBCs), resulting in reduced oxygen-carrying capacity of the blood. Anemia can result from inadequate RBC production, increased RBC destruction, or blood loss. It can be a manifestation of systemic disorders, such as infection, chronic renal disease, or malignancy. Anemia is often a sign of underlying pathology, and rapid diagnosis of the cause may be essential.

Figure 122-1 shows the functional classification of anemia. This chapter focuses on some of the most common causes of anemia—IDA, vitamin B_{12} or folic acid deficiency, and anemia of inflammation (AI) (eg, anemia of chronic disease [ACD]). Some of the other common causes of anemia are discussed in other chapters (cancer, renal disease). Drugs can also cause hematologic disorders, including anemia.

Characteristic changes in the RBC size based on erythrocyte indices can be the first step in the morphologic classification and understanding of the anemia. Anemia can be classified by RBC size such as macrocytic, normocytic, or microcytic. Both vitamin B_{12} deficiency and folic acid deficiency are macrocytic anemias. An example of a microcytic anemia is iron deficiency, whereas a normocytic anemia may be associated with recent blood loss or chronic disease. More than one etiology of anemia can occur concurrently. Mixed anemias occur more commonly in older adults.

Microcytic anemias result from a quantitative deficiency in Hb synthesis, usually due to iron deficiency or impaired iron utilization. As a result, erythrocytes containing insufficient Hb are formed. Microcytosis and hypochromia are the morphologic abnormalities that provide evidence of impaired Hb synthesis.

Macrocytic anemias can be divided into megaloblastic and nonmegaloblastic anemias. The type of macrocytic anemia can be distinguished microscopically by peripheral blood smear examination. Megaloblasts are distinctive cells that express a biochemical abnormality of impaired DNA synthesis, resulting in unbalanced cell growth. Megaloblastic anemias may affect all hematopoietic cell lines. The most common causes of megaloblastic anemia discussed in this chapter are vitamin B_{12} and folate deficiency. Nonmegaloblastic macrocytic anemias may arise from liver disease, hypothyroidism, hemolytic processes, and alcoholism.

MATURATION AND DEVELOPMENT OF RED BLOOD CELLS

In adults, RBCs are formed in the marrow of the vertebrae, ribs, sternum, clavicle, pelvic (iliac) crest, and proximal epiphyses of the long bones. In children, most bone marrow space is hematopoietically active to meet increased RBC requirements.

In normal RBC formation, a pluripotent stem cell yields an erythroid burst-forming unit. Erythropoietin (EPO) and cytokines such as interleukin-3 and granulocyte-macrophage colony-stimulating factor stimulate this cell to form an erythroid colony-forming unit in the marrow (Fig. 122-2). During this process, the nucleus becomes smaller with each division, finally disappearing in the normal erythrocyte. Hb and iron are incorporated into the gradually maturing RBC, which eventually is released from the marrow into the circulating blood as a reticulocyte. The maturation process usually takes about 1 week. The reticulocyte loses its nucleus and becomes an erythrocyte within several days. The circulating erythrocyte is a non-nucleated, nondividing cell. More than 90% of the protein content of the erythrocyte consists of the oxygen-carrying molecule Hb. Erythrocytes have a normal survival time of about 120 days.[9]

Stimulation of Erythropoiesis

The hormone EPO, 90% of which is produced by the kidneys, initiates and stimulates RBC production. Erythropoiesis is regulated by a feedback loop (Fig. 122-3). The primary mechanism of action of EPO is to prevent apoptosis, or programmed cell death, of erythroid precursor cells and allow their proliferation and subsequent maturation. A decrease in tissue oxygen concentration signals the kidneys to increase the production and release of EPO into the plasma, which increases production and maturation of RBCs. Under normal circumstances, the RBC mass is kept at an almost constant level by EPO matching new erythrocyte production to the natural rate of loss of RBCs. Early appearance of large quantities of reticulocytes in the peripheral circulation (reticulocytosis) is an indication of increased RBC production.[9]

Incorporation of Iron into Heme

Iron is an essential part of Hb. The specific plasma transport protein transferrin delivers iron to the bone marrow for incorporation into the Hb molecule. Transferrin enters cells by binding to transferrin receptors, which circulate and then attach to cells needing iron. Fewer transferrin receptors are present on the surface of cells that do not need iron, thus preventing iron-replete cells from receiving excess iron.[10]

Circulating transferrin normally is about 30% saturated with iron. Transferrin delivers extra iron to other body storage sites, such as the liver, marrow, and spleen, for later use. This iron is stored within macrophages as ferritin or hemosiderin. Ferritin consists of a Fe^{3+} hydroxyphosphate core surrounded by a protein shell called *apoferritin*. Hemosiderin can be described as compacted ferritin molecules with an even greater iron-to-protein shell ratio. Physiologically it is a more stable, but less available, form of storage iron. Since total body iron storage is generally reflected by ferritin levels, low serum ferritin levels provide strong evidence of IDA.[9]

Normal Destruction of Red Blood Cells

Phagocytic breakdown destroys older blood cells, primarily in the spleen but also in the marrow (Fig. 122-4). The Hb in RBCs destroyed by intravascular hemolysis becomes attached to haptoglobin and is carried back to the marrow for processing in the normal manner.[11]

DIAGNOSIS OF ANEMIA

General Presentation

History, physical examination, and laboratory testing are used to evaluate the patient with anemia. The workup determines if the patient is bleeding and investigates potential causes of the anemia, such as increased RBC destruction, bone marrow suppression, and iron deficiency. Diet can be important in identifying the causes of anemia. Additionally, information about concurrent nonhematologic disease states and a drug history are essential when evaluating the cause of the anemia (Chapter e125, “Drug-Induced Hematologic Disorders“). History of blood transfusions and exposure to toxic chemicals also should be obtained.

Presenting signs and symptoms of anemia depend on its rate of development and the patient’s age and cardiovascular status. The severity of symptoms does not always correlate with the degree of anemia. Healthy patients may acclimate to low Hb concentrations if the anemia develops slowly. Mild anemia often is associated with no clinical symptoms and may be found incidentally upon obtaining a complete blood count (CBC) for other reasons. The signs and symptoms in older adults with anemia may be incorrectly attributed to their age or concomitant disease states. Older adults may not tolerate lower levels of Hb in the same way that younger persons do. Similarly, patients with cardiac or pulmonary disease may be less tolerant of mild anemia. Premature infants with anemia may be asymptomatic or have tachycardia, poor weight gain, increased supplemental oxygen needs, or episodes of apnea or bradycardia.

② Anemia of rapid onset is most likely to present with cardiopulmonary symptoms such as palpitations, angina, lightheadedness, and shortness of breath due to decreased oxygen delivery to tissues or hypovolemia in those with acute bleeding. The patient also may have tachycardia and hypotension.

If onset is more chronic, presenting symptoms may include fatigue, weakness, headache, orthopnea, dyspnea on exertion, vertigo, faintness, sensitivity to cold, and pallor. These traditional signs of anemia have limited sensitivity and specificity and may be misinterpreted. With chronic bleeding, equilibration within the extravascular space occurs, so cardiopulmonary symptoms are less common.

Possible manifestations of IDA include glossal pain, smooth tongue, reduced salivary flow, pica (compulsive eating of nonfood items), and pagophagia (compulsive eating of ice). These symptoms are not likely to appear unless the anemia is severe.

Neurologic findings in vitamin B_{12} deficiency may precede hematologic changes. Early neurologic findings may include numbness and paraesthesias, which are typically bilateral and affect lower limbs more frequently. Ataxia, spasticity, diminished vibratory sense, decreased proprioception, and imbalance may occur later as demyelination of the dorsal columns and corticospinal tract develop. Vision changes may result from optic nerve involvement. Psychiatric findings include irritability, personality changes, memory impairment, depression, and infrequently, psychosis.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Anemia

General

- Patients may be asymptomatic or have vague complaints
- Patients with vitamin B_{12} deficiency may develop neurologic complications
- In AI, signs and symptoms of the underlying disorder often overshadow those of the anemia

Symptoms

- Decreased exercise tolerance
- Fatigue
- Dizziness
- Irritability
- Weakness
- Palpitations
- Vertigo
- Shortness of breath
- Chest pain
- Neurologic symptoms in vitamin B_{12} deficiency

Signs

- Tachycardia

- Pale appearance (most prominent in conjunctivae)
- Decreased mental acuity
- Increased intensity of some cardiac valvular murmurs
- Diminished vibratory sense or gait abnormality in vitamin B_{12} deficiency

Laboratory Tests

- Hemoglobin, hematocrit, and RBC indices may remain normal early in the disease and then decrease as the anemia progresses
- Serum iron is low in IDA and AI
- Ferritin levels are low in IDA and normal or elevated in AI
- Total iron-binding capacity is high in IDA and is low or normal in AI
- Mean cell volume is elevated in vitamin B_{12} deficiency and folate deficiency
- Vitamin B_{12} and folate levels are low in their respective types of anemia
- Homocysteine is elevated in vitamin B_{12} deficiency and folate deficiency
- Methylmalonic acid is elevated in vitamin B_{12} deficiency

Laboratory Evaluation

The initial evaluation of anemia involves a CBC (including RBC indices), reticulocyte index, and possibly an examination of a stool sample for occult blood if bleeding is suspected. The results of the initial evaluation determine the need for other studies, such as examination of a peripheral blood smear. Based on laboratory test results, anemia can be categorized into three functional defects: RBC production failure (hypoproliferative), cell maturation ineffectiveness, or increased RBC destruction or loss (see Fig. 122-1).

Figure 122-5 shows a broad, general algorithm for the diagnosis of anemia based on laboratory data. There are many exceptions and additions to this algorithm, but it can serve as a guide to the typical presentation of common types and causes of anemia. The algorithm is less useful in the presence of more than one cause of anemia.

Hemoglobin

Values given for Hb represent the amount of Hb per volume of whole blood. The higher values seen in males are due to stimulation of RBC production by androgenic steroids, while the lower values in females reflect the decrease in Hb as a result of blood loss during menstruation. The Hb level can be used as a rough estimate of the oxygen-carrying capacity of blood. Hb levels may be diminished because of a decreased quantity of Hb per RBC or a decrease in the actual number of RBCs.

Hematocrit

Expressed as a percentage, hematocrit (Hct) is the actual volume of RBCs in a unit volume of whole blood. It is generally about three times the Hb value (when Hb is expressed in g/dL). An alteration in this ratio may occur with abnormal cell size or shape and often indicates pathology. A low Hct indicates a reduction in either the number or the size of RBCs or an increase in plasma volume.

Red Blood Cell Count

The RBC count is an indirect estimate of the Hb content of the blood; it is an actual count of RBCs per unit of blood.

Red Blood Cell Indices

Wintrobe indices describe the size and Hb content of the RBCs and are calculated from the Hb, Hct, and RBC count. RBC indices, such as mean corpuscular volume (MCV) and mean corpuscular hemoglobin (MCH), are single mean values that do not express the variation that can occur in cells.

Mean Corpuscular Volume

MCV represents the average volume of RBCs. It may reflect changes in MCH. Cells are considered macrocytic if they are larger than normal, microcytic if they are smaller than normal, and normocytic if their size falls within normal limits. Folic acid- and vitamin B_{12}–deficiency anemias yield macrocytic cells, whereas iron deficiency is an example of a microcytic anemia. When IDA (decreased MCV) is accompanied by folate deficiency (increased MCV), the overall MCV may be normal. Failure to understand that the MCV represents an average RBC size can cause the clinician to potentially overlook some causes of the anemia.

Mean Corpuscular Hemoglobin

MCH is the amount of Hb in a RBC, and usually increases or decreases with the MCV. Two morphologic changes, microcytosis and hypochromia, can reduce MCH. A microcytic cell contains less Hb because it is a smaller cell, while a hypochromic cell has a low MCH because of the decreased concentration of Hb present in the cell. Cells can be both microcytic and hypochromic, as seen with IDA. The MCH alone cannot distinguish between microcytosis and hypochromia. The most common cause of an elevated MCH is macrocytosis (eg, vitamin B_{12} or folate deficiency).

Mean Corpuscular Hemoglobin Concentration

The concentration of Hb per volume of cells is the mean cell Hb concentration (MCHC). Because MCHC is independent of cell size, it is more useful than MCH in distinguishing between microcytosis and hypochromia. A low MCHC indicates hypochromia; a microcyte with a normal Hb concentration will have a low MCH but a normal MCHC. A decreased MCHC is seen most often in IDA.

Total Reticulocyte Count

The total reticulocyte count is an indirect assessment of new RBC production. It reflects how quickly immature RBCs (reticulocytes) are produced by bone marrow and released into the blood. Reticulocytes circulate in the blood about 2 days before maturing into RBCs. About 1% of RBCs are normally replaced daily, representing a reticulocyte count of 1%. The reticulocyte count in normocytic anemia can differentiate hypoproliferative marrow from a compensatory marrow response to anemia (see Fig. 122-5). A lack of reticulocytosis in anemia indicates impaired RBC production. Examples include iron deficiency, B_{12} deficiency, ACD, malnutrition, renal insufficiency, and malignancy. A high reticulocyte count may be seen in acute blood loss or hemolysis.

Red Blood Cell Distribution Width

The higher the red blood cell distribution width (RDW), the more variable is the size of the RBCs. The RDW increases in early IDA because of the release of large, immature, nucleated RBCs to compensate for the anemia, but this change is not specific for IDA. The RDW can also be helpful in the diagnosis of a mixed anemia. A patient can have a normal MCV yet have a wide RDW. This finding indicates the presence of microcytes and macrocytes, which would yield a "normal" average RBC size. The use of RDW to distinguish IDA from ACD is not recommended.

Peripheral Blood Smear

The peripheral blood smear can supplement other clinical data and help establish a diagnosis. Peripheral blood smears provide information on the functional status of the bone marrow and defects in RBC production. Additionally, it provides information on variations in cell size (anisocytosis) and shape (poikilocytosis). Blood smears are placed on a microscope slide and stained as appropriate. Morphologic examination includes assessment of size, shape, and color. The extent of anisocytosis correlates with increased range of cell sizes. Poikilocytosis can suggest a defect in the maturation of RBC precursors in the bone marrow or the presence of hemolysis.

Serum Iron

The level of serum iron is the concentration of iron bound to transferrin. Transferrin is normally about one-third bound (saturated) to iron. The serum iron level of many patients with IDA may remain within the lower limits of normal because a considerable amount of time is required to deplete iron stores. Serum iron levels show diurnal variation (higher in the morning, lower in the afternoon), but this variation is probably not clinically significant.[12] Since serum iron levels are decreased by infection and inflammation, serum iron levels are best interpreted in conjunction with the total iron-binding capacity (TIBC). The serum iron level decreases with IDA and ACD and increases with hemolytic anemias and iron overload.

Total Iron-Binding Capacity

TIBC is an indirect measurement of the iron-binding capacity of serum transferrin. Normally, about 30% of available iron binding sites are filled. With this laboratory test, all binding sites are filled to measure TIBC; the excess (unbound) iron is then removed and the serum iron concentration determined. Unlike the serum iron level, the TIBC does not fluctuate over hours or days. TIBC usually is higher than normal when body iron stores are low. The finding of a low serum iron level and a high TIBC suggests IDA. The TIBC is actually a measurement of protein serum transferrin, which can be affected by a variety of factors. Patients with infection, malignancy, inflammation, liver disease, and uremia may have a decreased TIBC and a decreased serum iron level, which are consistent with the diagnosis of ACD.

Percentage Transferrin Saturation

The ratio of serum iron level to TIBC indicates transferrin saturation. It reflects the extent to which iron-binding sites are occupied on transferrin and indicates the amount of iron readily available for erythropoiesis. It is expressed as a percentage, as described in the following formula:

$$\text{Transferrin saturation} = \frac{\text{serum iron}}{\text{TIBC}} \times 100$$
Transferrin saturation=serum ironTIBC×100

Transferrin normally is 20% to 50% saturated with iron. In IDA, transferrin saturation of 15% or lower is commonly seen.[11] Transferrin saturation is a less sensitive and specific marker of iron deficiency than ferritin levels.

Serum Ferritin

The serum concentration of ferritin (storage iron) is proportional to total iron stores and therefore is the best indicator of iron deficiency or iron overload. Ferritin levels indicate the amount of iron stored in the liver, spleen, and bone marrow cells. Low serum ferritin levels are virtually diagnostic of IDA. In contrast, serum iron levels may decrease in both IDA and ACD. Since serum ferritin is an acute phase reactant, chronic infection or inflammation can increase its concentration independent of iron status, masking depleted tissue stores. This limits the utility of the serum ferritin if the level is normal or high for a chronically ill patient. For these patients, iron, even if present in these tissue stores, may not be available for erythropoiesis.

Folic Acid

The results of folic acid measurements vary depending on the assay method used. Decreased serum folic acid levels (less than 4 ng/mL [9 nmol/L]) indicate a folate deficiency anemia that may coexist with a vitamin B_{12}–deficiency anemia. Erythrocyte folic acid levels are less variable than serum levels because they are slow to decrease in an acute process such as drug-induced folic acid deficiency and slow to increase with oral folic acid replacement. In addition, erythrocyte folic acid levels have the theoretical advantage of less susceptibility to rapid changes in diet and alcohol intake. Limitations with sensitivity and specificity do exist with measurements of erythrocyte folate. If the serum folate concentration is normal for a patient with suspected folate deficiency, then the erythrocyte folate level should be measured.[13]

Vitamin B_{12}

Low levels (less than 200 pg/mL [148 pmol/L]) of vitamin B_{12} (cyanocobalamin or cobalamin) indicate deficiency. However, a deficiency may exist prior to the recognition of low serum levels. Serum values are maintained at the expense of vitamin B_{12} tissue stores. Vitamin B_{12} and folate deficiency may overlap, thus serum levels of both vitamins should be determined. Vitamin B_{12} levels may be falsely low with folate deficiency and pregnancy.[11]

Schilling Test

This test used to be the "gold standard" for assessing vitamin B_{12} absorption. Due to its cost, unavailable test components, and complexity, the test is no longer available.[14]

Homocysteine

Vitamin B_{12} and folate are required for the conversion of homocysteine to methionine. Increased serum homocysteine may suggest vitamin B_{12} or folate deficiency. Homocysteine levels can also be elevated in patients with vitamin B_6 deficiency, renal failure, and hypothyroidism.[15]

Methylmalonic Acid

A vitamin B_{12} coenzyme is needed to convert methylmalonyl coenzyme A to succinyl coenzyme A. Patients with vitamin B_{12} deficiency have increased concentrations of serum methylmalonic acid (MMA), which is a more specific marker for vitamin B_{12} deficiency than homocysteine. MMA levels are not elevated in folate deficiency because folate does not participate in MMA metabolism. Levels of both MMA and homocysteine usually are elevated prior to the development of hematologic abnormalities and reductions in serum vitamin B_{12} levels.[11]

IRON-DEFICIENCY ANEMIA

Epidemiology

Iron deficiency is the most common nutritional deficiency in developing and developed countries. Data from the National Health and Nutrition Examination Survey (NHANES) indicate the prevalence of iron deficiency in the United States in toddlers (1-2 years) and women of childbearing age is 7% and 12%, respectively.[16] Iron deficiency may precede the appearance of anemia because of the wide normal ranges for Hb and Hct.

Iron Balance

The normal iron content of the body is about 3 to 4 g. Iron is a component of Hb, myoglobin, and cytochromes. About 2 g of the iron exists in the form of Hb, and about 130 mg exists as iron-containing proteins such as myoglobin. About 3 mg of iron is bound to transferrin in plasma, and 1,000 mg of iron exists as storage iron in the form of ferritin or hemosiderin. The rest of the iron is stored in other tissues such as cytochromes.[12] Due to the toxicity of inorganic iron, the body has an intricate system for iron absorption, transport, storage, assimilation, and elimination. Hepcidin is a regulator of intestinal iron absorption, iron recycling, and iron mobilization from hepatic stores. It is a peptide hormone made in the liver, distributed in plasma, and excreted in urine. Hepcidin inhibits efflux of iron through ferroportin. Hepcidin synthesis is increased by iron loading and inflammation and decreased by iron deficiency and erythropoietic activity. Hepcidin is induced during infections and inflammation, which allows iron to sequester in macrophages, hepatocytes, and enterocytes.[158] As a result, hepcidin is likely an important mediator of AI. Hepcidin is usually suppressed in IDA.[17] Hepcidin testing is not routinely available.[18]

Most people lose about 1 mg of iron daily. Menstruating women can lose up to 0.6% to 2.5% more per day. Pregnancy requires additional iron and a blood donation can result in as much as 250 mg of iron loss;[19] these individuals are at higher risk for deficiency.

The daily recommended dietary allowance for iron is 8 mg in adult males and postmenopausal females and 18 mg in menstruating females. Children require more iron because of growth-related increases in blood volume, and pregnant women have an increased iron demand brought about by fetal development. In the absence of hemochromatosis, iron overload does not occur because only the amount of iron lost per day is absorbed. The amount of iron absorbed from food depends on body stores, the rate of RBC production, the type of iron provided in the diet, and the presence of any substances that may enhance or inhibit iron absorption.

Heme iron is found in meat, fish, and poultry, and is about three times more absorbable than the nonheme iron found in vegetables, fruits, dried beans, nuts, grain products, and dietary supplements. Gastric acid and other dietary components such as ascorbic acid increase the absorption of nonheme iron. Dietary components that form insoluble complexes with iron (phytates, tannates, and phosphates) decrease absorption. Phytates, a natural component of grains, brans, and some vegetables, can form poorly absorbed complexes and partially explain the increased prevalence of IDA in poorer countries, where grains and vegetables compose a disproportionate amount of the normal diet. Polyphenols bind iron and decrease nonheme iron absorption when large amounts of tea or coffee are consumed with a meal. Although the mechanism is unknown, calcium inhibits absorption of both heme and nonheme iron. Finally, because gastric acid improves iron absorption, patients who have had a gastrectomy or achlorhydria have decreased iron absorption.[20,21]

Etiology

Iron deficiency results from prolonged negative iron balance, which can occur due to increased iron demand or hematopoiesis, increased loss, or decreased intake/absorption. The onset of iron deficiency depends on an individual's initial iron stores and the imbalance between iron absorption and loss. Multiple etiologic factors usually are involved. Certain groups at higher risk for iron deficiency include children younger than 2 years, adolescent girls, pregnant/lactating females, and those older than 65 years. Blood loss should initially be considered a cause of IDA in adults.[22] Blood loss may occur as a result of many disorders, including trauma, hemorrhoids, peptic ulcers, gastritis, GI malignancies, arteriovenous malformations, diverticular disease, copious menstrual flow, nosebleeds, and postpartum bleeding. In less industrialized nations, the risk of IDA is largely related to dietary factors.

Pregnant women should be screened for anemia at their first prenatal visit, but the United States Preventive Services Task Force (USPSTF) no longer recommends routine screening for IDA in all asymptomatic pregnant women.[23] If a pregnant patient is anemic on screening, they should be evaluated for all types of anemia, with iron deficiency being the most common. The Centers for Disease Control and Prevention (CDC) recommends initiation of low-dose iron supplements or prenatal vitamins with 30 mg/day of iron at each woman's first prenatal visit to compensate for the increased iron demands during pregnancy.[24]

Medication history, specifically regarding recent or past use of iron, alcohol, corticosteroids, anticoagulants, aspirin, and nonsteroidal anti-inflammatory drugs (NSAIDs), is a vital part of the history to assess bleeding risk. Other possible causes of hypochromic microcytic anemia include AI, thalassemia, sideroblastic anemia, and heavy metal (mostly lead) poisoning (see Fig. 122-4).

Pathophysiology

Iron is vital to the function of all cells. Manifestations of iron deficiency occur in three stages. In the initial stage, iron stores are reduced without reduced serum iron levels and can be assessed with serum ferritin measurement. The stores allow iron to be utilized when there is an increased need for Hb synthesis. Once stores are depleted, there still is adequate iron from daily RBC turnover for Hb synthesis. Further iron losses would make the patient vulnerable to anemia development. In the second stage, iron deficiency occurs when iron stores are depleted, and Hb is above the lower limit of normal for the population, but may be reduced for a given patient. Findings include reduced transferrin saturation and increased TIBC. The third stage occurs when the Hb falls to less than normal values.

Laboratory Findings

③ Abnormal laboratory findings for patients with IDA generally include low serum iron and ferritin levels and high TIBC. In the early stages of IDA, RBC size is not changed. Low ferritin concentration is the earliest and most sensitive indicator of iron deficiency. However, ferritin may not correlate with iron stores in the bone marrow because renal or hepatic disease, malignancies, infection, or inflammatory processes may increase ferritin values.[12] Hb, Hct, and RBC indices usually remain normal in early stages. In the later stages of IDA, Hb, and Hct fall below normal values, and a microcytic hypochromic anemia develops. Even slightly abnormal Hb and Hct levels may indicate significant depletion of iron stores and should not be ignored. In terms of RBC indices, MCV is reduced earlier in IDA than Hb concentration.

Transferrin saturation (ie, serum iron level divided by the TIBC) is helpful for assessing IDA. Low values may indicate IDA, although low serum transferrin saturation values also may be present in inflammatory disorders. The TIBC may help to differentiate the diagnosis in these patients. Elevated TIBC levels suggest IDA, while low values represent inflammatory disease.

Treatment

Desired Outcomes

The outcomes for all types of anemia include reversal of hematologic parameters to normal, return of normal function and quality of life, and prevention or reversal of long-term complications, such as neurologic complications of vitamin B_{12} deficiency.

Dietary Supplementation and Oral Iron Preparations

The severity and cause of IDA determine the approach to treatment. Treatment is focused on replenishing iron stores. Because iron deficiency can be an early sign of other illnesses, treatment of the underlying disease may aid in the correction of iron deficiency.

Treatment of IDA usually consists of administration of oral or parenteral iron preparations. Examples of foods that are high in iron include animal liver, fortified cereals/oatmeal, beef, eggs, spinach, lentils, tofu, and beans. Iron is best absorbed from meat, fish, and poultry. These foods as well as certain iron-fortified cereals can help treat IDA if diet is a major factor in deficiency. Milk and tea reduce absorption of iron and should be consumed in moderation. In many cases of IDA, oral administration of iron therapy with soluble Fe^{2+} iron salts is an appropriate first step.

Fe^{2+} sulfate, succinate, lactate, fumarate, glutamate, and gluconate have similar oral absorption. Ferric citrate was approved by the Food and Drug

Administration (FDA) in 2017 to treat IDA in adults with chronic kidney disease who are not on dialysis (see Chapter 63). Iron is best absorbed in the reduced Fe^{2+} form, with maximal absorption occurring in the duodenum, primarily due to the acidic medium of the stomach. Slow-release, sustained-release, or enteric coated iron preparations may not undergo sufficient dissolution until they reach the small intestine. In the alkaline environment of the small intestine, iron tends to form insoluble complexes, which significantly reduces absorption. The dose of iron replacement therapy depends on the patient's ability to tolerate the administered iron. Tolerance of iron salts improves with a small initial dose and gradual escalation to the full dose. For patients with IDA, the generally recommended dose is about 150 to 200 mg of elemental iron daily, usually in two or three divided doses to maximize tolerability. If patients cannot tolerate this daily dose of elemental iron, smaller amounts of elemental iron (eg, single 325-mg tablet of Fe^{2+}sulfate) usually are sufficient to replace iron stores, although at a slower rate. Table 122-1 lists the percentage of elemental iron of commonly available iron salts. Iron preferably is administered at least 1 hour before meals because food can interfere with iron absorption. Many patients must take iron with food because they experience GI upset when iron is administered on an empty stomach.

TABLE 122-1

Oral Iron Products

Iron Salt	Percent Elemental Iron	Common Formulations and Elemental Iron Provided
Ferrous sulfate	20	60-65 mg/324-325 mg tablet 44 mg/5 mL elixir 15 mg/1 mL solution
Ferrous gluconate	12	38 mg/325 mg tablet 28-29 mg/240-246 mg tablet
Ferrous fumarate	33	66 mg/200 mg tablet 106 mg/324-325 mg tablet
Ferric maltol	100	30 mg/30 mg

Lower amounts of iron can be given and produce similar results with better tolerability. Hepicidin, a protein that regulates iron absorption, may play a role in oral iron dosing. A large dose of iron in the morning may elevate hepicidin levels and prevent further iron absorption of subsequent doses for at least the rest of the day, potentially up to 48 hours later.[25] Furthermore, once daily dosing of iron may result in a lower amount of iron being absorbed versus every other day dosing.[26] These studies have led some to propose that oral iron could be dosed every other day, particularly if the patient has difficulty tolerating a larger daily dose of oral iron. However, no long-term studies have been conducted to support this dosing strategy.

Adverse drug reactions to therapeutic doses of iron are primarily GI in nature and consist of dark discoloration of feces, constipation or diarrhea, nausea, and vomiting. GI effects usually are common, dose-related, and are similar among iron salts when equivalent amounts of elemental iron are administered. Administration of smaller amounts of iron with each dose or administration with meals may minimize these adverse effects. Histamine-2 blockers or proton-pump inhibitors reduce gastric acidity and may impair iron absorption. Table 122-2 lists important drug interactions with iron.

TABLE 122-2

Iron Salt-Drug Interactions

Drugs That Decrease Iron Absorption	Drugs Affected by Iron
Al^-, Mg^-, and Ca^{2+}-containing antacids Tetracycline and doxycycline Histamine$_2$ antagonists Proton-pump inhibitors Cholestyramine	Levodopa ↓ (chelates with iron) Methyldopa ↓ (decreases efficacy of methyldopa) Levothyroxine ↓ (decreased efficacy of levothyroxine) Penicillamine ↓ (chelates with iron) Fluoroquinolones ↓ (forms ferric ion quinolone complex) Tetracycline and doxycycline ↓ (when administered within 2 hours of iron salt)

Failure to respond to iron treatment regimens necessitates reevaluation of the patient's condition. Common causes of treatment failure include poor patient adherence, inability to absorb iron, incorrect diagnosis, continued bleeding, or a concurrent inflammatory condition that impairs a full response. Even when iron deficiency is present, response may be impaired when a coexisting cause for anemia exists. Rarely a patient has diminished ability to absorb iron, most often due to previous gastrectomy, such as gastric bypass surgery, or celiac disease. Regardless of the form of oral therapy used, treatment should continue for 3 to 6 months after the anemia is resolved to allow for repletion of iron stores and to prevent relapse. Patients should be instructed to store oral iron out of reach of children and pets as small amounts can result in a fatal overdose. Treatment for acute iron poisoning is discussed in Chapter e8, "Clinical Toxicology."

Parenteral Iron Therapy

Indications for parenteral iron therapy include intolerance to oral, malabsorption, and nonadherence. Patients with significant blood loss who refuse transfusions and cannot take oral iron therapy also may require parenteral iron therapy. Parenteral iron therapy should also be considered, possibly first line, in patients with inflammatory bowel disease and those with gastric bypass/gastric resection due to poor oral absorption.[27] Parenteral iron therapy is also used for patients with chronic kidney disease (see Chapter 63), especially those undergoing hemodialysis, and for some cancer patients receiving chemotherapy on erythropoiesis-stimulating agents (ESAs; Chapter 150). Seven different parenteral iron preparations available in the United States are low molecular weight iron dextran, ferric gluconate, iron sucrose, ferumoxytol, ferric derisomaltose, ferric pyrophosphate citrate, and ferric carboxymaltose (Table 63-4). They differ in their molecular size, pharmacokinetics, bioavailability, and adverse effect profiles. Although toxicity profiles of these agents differ, clinical studies indicate that each is efficacious. High molecular weight iron dextran parenteral preparations have been previously associated with more anaphylactic reactions. The high molecular weight product is no longer available. The low molecular weight has a lower risk of these reactions, but it requires a test dose prior to full dose administration. Fatal reactions have also occurred in patients who tolerated the test dose with the high molecular weight product. The safety profile of parenteral iron is largely assessed by spontaneous reports to the FDA and observational studies. All parenteral iron preparations carry a risk for anaphylactic reactions but the risk is lower than that for high molecular weight iron dextran.[28,29] The FDA recommends that resuscitation equipment and trained staff be available during administration of all iron dextran preparations. A concern with parenteral iron is that iron may be released too quickly and overload the ability of transferrin to bind it, leading to free iron reactions that can interfere with neutrophil function.

$(\text{mg}) = \text{whole blood hemoglobin deficit}(\text{g/L}) \times \text{body weight}(\text{kg}) \times 0.22$(mg)=whole blood hemoglobin deficit(g/L)×body weight(kg)×0.22

Iron dextran, a complex of Fe^{3+} hydroxide and the carbohydrate dextran, contains 50 mg of iron/mL and can be given via the intramuscular or IV route. Different brands of iron dextran are available and differ in their molecular weight. They are not interchangeable. The intramuscular route is no longer used routinely and requires Z-tract injection technique.[30] Methods of IV administration include multiple injections or an infusion of a diluted preparation. This latter method often is referred to as total dose infusion.

Total replacement doses of IV iron dextran can be given as a single dose, but this method of administration is not FDA approved. A test dose is still required. Patients who receive total dose infusions are at higher risk for adverse drug reactions, such as arthralgias, myalgias, flushing, malaise, and fever. Patients with preexisting immune-mediated diseases, such as active rheumatoid arthritis or systemic lupus erythematosus, are at high risk for adverse drug reactions because of their hyperreactive immune response.[31]

Ferric gluconate is a complex of iron bound to one gluconate and four sucrose molecules in a repeating pattern. Ferric gluconate is available in an aqueous solution. No direct transfer of iron from the Fe^{3+} gluconate to transferrin occurs. The complex is taken up quickly by the mononuclear phagocytic system and has a half-life of about 1 hour in the bloodstream. Ferric gluconate produces fewer anaphylactic reactions than iron dextran does. Adverse drug reactions of sodium ferric gluconate include cramps, nausea, vomiting, flushing, hypotension, intense upper gastric pain, rash, and pruritus.[32]

Iron sucrose is a polynuclear iron (III) hydroxide in sucrose complex. Following IV administration of iron sucrose, the iron is released directly from the circulating iron sucrose to transferrin and is taken up by the mononuclear phagocytic system and metabolized. The half-life is about 6 hours, with a volume of distribution similar to that of iron dextran.[33] Adverse drug reactions include leg cramps and hypotension.

Ferumoxytol is FDA-approved to treat iron deficiency in adults with chronic kidney disease and adults with IDA who have not responded to oral iron. No test dose is required but anaphylaxis can occur and patients should be observed for at least 30 minutes after each dose. A warning was added in 2015 due to case reports of fatal and nonfatal anaphylactic reactions to the product. It should not be used in patients who previously had an allergic reaction to other iron preparations. Ferumoxytol can also interfere with magnetic resonance imaging (MRI) scans and the radiologist should be notified if the patient has received this medication within 3 months of the scan.[34]

Ferric carboxymaltose received approval for treatment of IDA in those who have failed oral iron therapy or who have intolerance to oral therapy. The approval of this product was delayed due to hypophosphatemia seen in clinical trials. No additional warnings were required and no clinical issues related to hypophosphatemia have been reported. This product can also be given in a two-dose regimen or a single-dose regimen. It is also approved for chronic kidney disease patients not on hemodialysis.[35]

Ferric derisomaltose is approved for patients with IDA who have intolerance to oral iron or an unsatisfactory response to oral iron, as well as patients with chronic kidney disease who do not depend on hemodialysis. This product can be given as a single- or multi-dose regimen.

Increased risk for infection is a concern with parenteral iron preparations because iron is a growth factor for some bacteria, but a meta-analysis reported that IV iron does not increase the risk for infection.[36] Parenteral iron products are discussed in more detail in Chapter 63.

MEGALOBLASTIC ANEMIAS

Macrocytic anemias are divided into megaloblastic and nonmegaloblastic anemias. Macrocytosis, as seen in megaloblastic anemias, is caused by abnormal DNA metabolism resulting from vitamin B_{12} or folate deficiency. It can also be caused by administration of various drugs, such as hydroxyurea, zidovudine, cytarabine, methotrexate, azathioprine, 6-mercaptopurine, and cladribine. In vitamin B_{12}– or folate-deficiency anemia, megaloblastosis results from interference with folic acid- and vitamin B_{12}–interdependent nucleic acid synthesis in the immature erythrocyte (Fig. 122-6).

FIGURE 122-6

Drug-induced megaloblastosis.

Although vitamin B_{12} and folate deficiency are common causes of macrocytosis, other possible causes must be considered if these deficiencies are not found. These can include aplastic anemia, myelodysplastic syndromes, alcohol abuse, and multiple myeloma. Macrocytosis is the most typical morphologic abnormality associated with excessive alcohol consumption. Even with adequate folate and vitamin B_{12} levels and the absence of liver disease, patients with high alcohol intake may present with an alcohol-induced macrocytosis. Cessation of alcohol ingestion resolves the macrocytosis within a couple of months.

Vitamin B_{12}–Deficiency Anemia

The exact prevalence of vitamin B_{12}–deficiency anemia in the United States is unknown. Risk increases with age.[37] One study conducted in the United States and the United Kingdom found that the prevalence of vitamin B_{12} deficiency increased from about 6% in adults younger than 60 years to 20% in those older than 60 years.[38] Gastric acid–suppressing agents may inhibit cobalamin release from food, and their use is associated with an increased risk. Older adults in the United States have a high prevalence (up to 15%) of elevated MMA levels and associated low or low-normal vitamin B_{12} levels, likely due to atrophic gastritis and malabsorption of food-bound vitamin B_{12}.[37]

Etiology

④ The three major causes of vitamin B_{12} deficiency are inadequate intake, malabsorption syndromes, and inadequate utilization. Inadequate dietary consumption of vitamin B_{12} is rare. It usually occurs only in patients who are strict vegans without supplementation, chronic alcoholics, and older adults who consume a "tea and toast" diet because of financial limitations or poor dentition. Decreased vitamin B_{12} absorption can occur with loss of intrinsic factor by autoimmune mechanisms (such as pernicious anemia, in which gastric parietal cells are selectively damaged), chronic atrophic gastritis, or stomach surgery. One of the most frequent causes of low serum B_{12} levels results from the inability of vitamin B_{12} to be cleaved and released from proteins in food because of inadequate gastric acid production. Treatment of *Helicobacter pylori* may improve vitamin B_{12} status because this bacterial infection is a cause of chronic gastritis.[39] Vitamin B_{12} deficiency may occasionally result from overgrowth of bacteria in the bowel that uses vitamin B_{12} or from injury or removal (from Crohn's disease or small bowel surgery, respectively) of ileal receptor sites where vitamin B_{12} and the intrinsic factor complex are absorbed. Blind loop syndrome, Whipple disease, Zollinger–Ellison syndrome, tapeworm infestations, intestinal resections, tropical sprue, surgical resection of the ileus, pancreatic insufficiency, inflammatory bowel disease, advanced liver disease, tuberculosis, and Crohn's disease may contribute to the development of vitamin B_{12} deficiency.[37] Metformin may reversibly decrease B_{12} absorption, likely due to its effects on the intestinal mucosa in the ileum and calcium homeostasis. Low B_{12} related to metformin can occur within months of starting the medication, but it is more likely after 5 years and some clinicians will monitor B_{12} in patients receiving long-term metformin therapy or those with a poor oral intake of vitamin B_{12}.[40] Proton pump inhibitors and histamine-2 receptor antagonists may also contribute to vitamin B_{12} deficiency because an acidic environment is needed for vitamin B_{12} to be absorbed in the GI tract from food.[41] Long term use of these agents for 2 or more years increases the risk of deficiency.[41]

Pathophysiology

Vitamin B_{12} works closely with folate in the synthesis of building blocks for DNA and RNA, is essential in maintaining the integrity of the neurologic system, and plays a role in fatty acid biosynthesis and energy production. It is a water-soluble vitamin obtained exogenously by ingestion of meat, fish, poultry, dairy products, and fortified cereals. The body stores several years of vitamin B_{12}, of which about 50% is in the liver. The recommended daily allowance is 2 μg in adults and 2.6 μg in pregnant or breast-feeding women. The average Western diet provides 5 to 15 μg of vitamin B_{12} daily, of which 1 to 5 μg is absorbed.[37] Vitamin B_{12} deficiency can take several years to develop following vitamin deprivation.

Once dietary cobalamin enters the stomach, pepsin and hydrochloric acid release the cobalamin from animal proteins. The cobalamin then binds with intrinsic factor that serves as a cell-directed carrier protein similar to transferrin for iron. This complex attaches to mucosal cell receptors in the distal ileum, the intrinsic factor is discarded, and the cobalamin is bound to transport proteins (transcobalamin I, II, and III). Passive diffusion is an alternate pathway for vitamin B_{12} absorption independent of intrinsic factor or an intact terminal ileum and accounts for about 1% of vitamin B_{12} absorption.[37]

Vitamin B_{12} deficiency can cause neurologic and hematologic complications. They usually start with bilateral paraesthesia in the extremities; deficits in proprioception and vibration can also be present. If not treated, this can progress to ataxia, dementia-like symptoms, psychosis, and vision loss. In children, prolonged deficiency can lead to poor brain development.[14,42] Patients with unexplained neuropathies should be evaluated for vitamin B_{12} deficiency.

Laboratory Findings

In macrocytic anemias, MCV is elevated, but some patients deficient in vitamin B_{12} may have a normal MCV. If there is a coexisting cause of microcytosis, the MCV may not be elevated.[36] A peripheral blood smear shows macrocytosis accompanied by hypersegmented polymorphonuclear leukocytes (one of the earliest and most specific indications of this disease), oval macrocytes, anisocytosis, and poikilocytosis. Serum lactate dehydrogenase and indirect bilirubin levels may be elevated as a result of hemolysis or ineffective erythropoiesis.[14] Other laboratory findings include a low reticulocyte count, low serum vitamin B_{12} level (less than 200 pg/mL [148 pmol/L]), and low Hct.

In the early stages of vitamin B_{12} deficiency, classic signs and symptoms of megaloblastic anemia may not be evident, and serum levels of vitamin B_{12} may be within normal limits or borderline low (200-300 pg/mL [148-221 pmol/L]). Therefore, measurement of MMA and homocysteine may be useful because these parameters are typically the first to change. Because MMA and homocysteine are involved in enzymatic reactions that depend on vitamin B_{12}, vitamin B_{12} deficiency leads to accumulation of these metabolites. Elevations in MMA are more specific for vitamin B_{12} deficiency. Homocysteine is also elevated in several other situations including folate deficiency, chronic renal disease, alcoholism, smoking, and use of steroid or cyclosporine therapy.[42]

Blood levels of vitamin B_{12} should be drawn for all patients with suspected vitamin B_{12} deficiency. Vitamin B_{12} values less than 200 pg/mL (148 pmol/L) are diagnostic for B_{12} deficiency. Subclinical vitamin B_{12} deficiency is sometimes found with vitamin B_{12} levels of 200 to 300 pg/mL (148-221 pmol/L).[43] Some patients with clinical B_{12} deficiency manifesting as neurological disease have normal hematological parameters.

The Schilling test was once performed to determine whether replacement of vitamin B_{12} should occur via an oral or parenteral route due to pernicious anemia, but evidence now shows that oral replacement is as efficacious as parenteral supplementation because of the vitamin B_{12} absorption pathway independent of intrinsic factor.[37,44]

Treatment

Early treatment is important because neurologic damage may be irreversible if the deficiency is not detected and corrected within months. In addition to replacement therapy, any underlying etiology that is treatable, such as bacterial overgrowth, should be corrected. Indications for starting oral or parenteral therapy include megaloblastic anemia or other hematologic abnormalities and neurologic disease from deficiency.[42] Those with borderline low levels of B_{12} but no hematologic abnormalities should be followed at yearly intervals; monitoring MMA and homocysteine may also be useful.[42] Patients should be counseled on the types of foods high in vitamin B_{12} content such as fortified cereals, fish, animal liver, milk, clams, and yogurt. Oral vitamin B_{12} replacement is indicated for those without neurologic complications or significant symptoms and can be used effectively to treat pernicious anemia because of passive absorption, independent of intrinsic factor.[15] Cyanocobalamin is used primarily in the United States while hydroxycobolamin may be used in other countries. The typical dose for oral therapy is cyanocobalamin 1,000 µg once daily. Higher doses of (1,000-2,000 µg) of vitamin B_{12} may be given to patients with malabsorption and is as effective as intramuscular administration in achieving hematologic and neurologic responses.[37,44] If vitamin B_{12} levels are marginally low and either MMA or both MMA and homocysteine levels are elevated, oral administration of 1,000 µg of vitamin B_{12} daily should be strongly considered.[45] Timed-release preparations of oral cobalamin should be avoided.[46] Nonprescription 1,000 µg cobalamin tablets are available, among several other strengths at a low cost. Oral replacement may be as effective as parenteral administration in achieving hematologic and neurologic responses.[37,38] However, parenteral therapy is usually given if patients have neurologic or severe anemia symptoms to protect against further progression. A commonly used initial parenteral vitamin B_{12} regimen consists of daily intramuscular or deep subcutaneous injections of 1,000 µg of cyanocobalamin for 1 week to saturate vitamin B_{12} stores in the body and resolve clinical manifestations of the deficiency. After that, it can be given weekly for 1 month and monthly thereafter for maintenance. The series of daily parenteral injections may be omitted if administration is difficult or inconvenient. In this case, the parenteral injection is then given weekly, sometimes for longer than 1 month. Patients can be instructed to give these injections at home to avoid the cost of an office visit and convenience. After symptoms have resolved and hematologic indices and vitamin B_{12} levels have normalized, patients can be converted from parenteral therapy to oral maintenance therapy.[47] When patients are converted from the parenteral to the oral form of cobalamin, oral cobalamin daily can be initiated on the due date of the next injection. Vitamin B_{12} should be continued for life in patients with pernicious anemia.

In addition to the oral and parenteral forms, vitamin B_{12} is available as a nasal spray for patients in remission following intramuscular vitamin B_{12} therapy who have no neurologic involvement. The nasal spray is administered once weekly. Intranasal administration should be avoided for patients with nasal diseases or those receiving medications intranasally in the same nostril. Patients should not administer the spray 1 hour before or after ingestion of hot foods or beverages, which can impair cobalamin absorption. The efficacy of the nasal spray formulation has not been well studied and may have variable absorption. It should be used for maintenance therapy only after hematologic parameters have normalized.

Potential adverse drug reactions with vitamin B_{12} replacement therapy are rare. Uncommon adverse drug reactions are headache, weakness, and hypokalemia.

Folic Acid Deficiency Anemia

Epidemiology

Folic acid deficiency is one of the most common vitamin deficiencies occurring in the United States, largely because of its association with excessive alcohol intake and pregnancy. Fortification of grain products in the 1990s increased folate intake across the United States. According to data from the National Health and Nutrition Examination Survey (NHANES), most people in the United States intake adequate dietary amounts of folate and only 0.5% of children aged 1 to 18 years have folate deficiency.[48]

Etiology

⑤ Major causes of folic acid deficiency include inadequate intake, decreased absorption, and increased folate requirements. Poor eating habits make this deficiency more common in older adults, teenagers whose diets consist of "junk food," and individuals with alcoholism, food insecurity, chronic illness, or dementia. Folic acid absorption may decrease for patients who have malabsorption syndromes or received certain drugs. In patients with alcoholism with poor dietary habits, alcohol interferes with folic acid absorption and utilization at the cellular level and decreases hepatic stores of folic acid.

Increased folate requirements may occur when the rate of cellular division is increased, as seen in pregnant women; patients with hemolytic anemia, malignancy, chronic inflammatory disorders such as Crohn's disease, rheumatoid arthritis, or psoriasis; patients undergoing long-term dialysis; burn patients; and adolescents and infants during their growth spurts. This hyperutilization eventually can lead to anemia, particularly when the daily intake of folate is borderline, resulting in inadequate replacement of folate stores.

Several drugs have been reported to cause a folic acid deficiency. Some drugs (eg, azathioprine, 6-mercaptopurine, 5-fluorouracil, hydroxyurea, and zidovudine) directly inhibit DNA synthesis. Other drugs are folate antagonists and inhibit dihydrofolate reductase; the most toxic is methotrexate (other examples include pentamidine, trimethoprim, and triamterene). A number of drugs (eg, phenytoin, carbamazepine, valproate, primidone) antagonize folate via poorly understood mechanisms but are thought to reduce vitamin absorption by the intestine (see Chapter e125). Since folic acid doses as low as 1 mg/day may affect serum phenytoin levels, routine folic acid supplementation is not generally recommended.[42] Alcohol can also interfere with folic acid absorption, likely through its effects on the intestinal mucosa.[41]

Pathophysiology

Folic acid is a water-soluble vitamin readily destroyed by cooking or processing. It is necessary for the production of DNA and RNA. It acts as a methyl donor to form methylcobalamin, which is used in the remethylation of homocysteine to methionine. Because humans are unable to synthesize sufficient folate to meet total daily requirements, they depend on dietary sources. Major dietary sources of folate include fresh, green leafy vegetables, citrus fruits, yeast, mushrooms, dairy products, and animal organs such as liver and kidney. Once absorbed, dietary folate must be converted to the active form tetrahydrofolate through a cobalamin-dependent reaction. In 1997, the United States mandated that grain products be fortified with folic acid to increase the dietary intake of folate. This amount of supplementation was chosen to decrease the incidence of neural tube defects without masking occult vitamin B_{12} deficiency.

As a result of grain product fortification, neural tube defect frequency has decreased by 25% to 30%.[49] Although body demands for folate are high because of high rates of RBC synthesis and turnover, the minimum daily requirement is 50 to 100 µg. In the general population, the recommended daily allowance for folate is 400 µg in nonpregnant females, 600 µg in pregnant females, and 500 µg in lactating females.[45] Because the body stores about 15 to 30 mg of folate, primarily in the liver, cessation of dietary folate intake can result in deficiency in months.[50]

Laboratory Findings

It is critically important to rule out vitamin B_{12} deficiency when folate deficiency is suspected to prevent neurologic complications developing from vitamin B_{12} deficiency. Laboratory changes associated with folate deficiency are similar to those seen in vitamin B_{12} deficiency, except serum vitamin B_{12} and MMA levels are normal. Serum folate levels less than 2 ng/mL (4.5 nmol/L) are considered low, although normal ranges may vary between institutions. The RBC folate level (less than 150 ng/mL [340 nmol/L]) also declines, and levels remain constant throughout the life span of the erythrocyte.[11] The RBC folate levels may not provide additional information beyond the serum folate level. If serum or erythrocyte folate levels are borderline, serum homocysteine usually is increased with a folic acid deficiency. If serum MMA levels also are elevated, vitamin B_{12} deficiency must be ruled out given that folate does not participate in MMA metabolism.

Treatment

Therapy for folic acid deficiency consists of administration of exogenous folic acid to normalize hematologic labs, replace body stores, and resolve signs and symptoms. In most cases, 1 mg daily is sufficient to replace stores; doses of 1 to 5 mg daily may be necessary in cases of deficiency due to malabsorption. Parenteral folic acid is available but rarely necessary. Synthetic folic acid is almost completely absorbed by the GI tract and is converted to tetrahydrofolate without cobalamin. Therapy should continue for about 4 months if the underlying cause of the deficiency can be identified and corrected to allow for clearance of all folate-deficient RBCs from the circulation. Examples of foods high in folic acid include beef liver, fortified cereals, lentils, green leafy vegetables, orange juice, and rice. They should be encouraged in the diet. Long-term folate administration may be necessary in patients with chronic conditions associated with increased folate requirements. Low-dose folate therapy (500 μg daily) can be administered when anticonvulsant drugs produce a megaloblastic anemia so that discontinuation of anticonvulsant therapy may not be necessary. Adverse drug reactions have not been reported with folic acid doses used for replacement therapy. It is considered nontoxic at high doses and is rapidly excreted in the urine.

Although megaloblastic anemia during pregnancy is rare, the most common cause is folate deficiency. Periconceptional folic acid supplementation is recommended to decrease the occurrence and recurrence of neural tube defects (eg, anencephaly and spinal bifida). Folic acid supplementation at a dose of 400 μg daily is recommended for all women. Women who have previously given birth to offspring with neural tube defects or those with a family history of neural tube defects should ingest 1 to 4 mg daily of folic acid.[49,51,52] Higher levels of folic acid supplementation should not be attained via ingestion of excess multivitamins because of the risk of fat-soluble vitamin toxicity.[52] Prenatal vitamins usually have a higher amount of folic acid as compared with general multivitamins to ensure adequate supplementation is attained. It is essential that women in their childbearing years maintain adequate folic acid intake.

ANEMIA OF INFLAMMATION

Epidemiology

⑥ AI is a term used to describe both ACD and anemia of critical illness. This term was developed to reflect the inflammatory process resulting in disturbances in iron homeostatis underlying both types of anemia. The onset of anemia of critical illness is rapid, generally over days, and often occurs in a hospital setting due to tissue damage and acute inflammatory changes. ACD has a similar mechanism, but develops over months to years from an underlying chronic condition. Globally, AI is one of the most common forms of anemia, particularly among older adults, although its prevalence is not known due to the complex and multifaceted nature of the disease. ACD is associated with common disease states that may mimic the symptoms of anemia, which causes the diagnosis of ACD to be sometimes overlooked in the outpatient setting. Anemia of critical illness is a common complication in critically ill patients and is found almost universally in this patient population.[53]

Etiology

AI is an anemia traditionally associated with infectious or inflammatory processes, tissue injury, and conditions associated with the release of proinflammatory cytokines. The etiology of AI can be multifactorial and the diagnosis is usually one of exclusion. A comprehensive history of the illness is important to help rule out other potential causes of anemia. Although it may be difficult to delineate between IDA and AI, it is important to exclude IDA as the true or competing etiology. Various conditions associated with ACD may predispose patients to blood loss (malignancy, GI blood loss from treatments with aspirin, NSAIDs, or corticosteroids). ACD is often observed in patients with diseases containing an inflammatory component lasting longer than 1 to 2 months, although it can occur in conditions with a more rapid onset of several weeks, such as pneumonia. Anemia associated with human immunodeficiency virus (HIV), autoimmune conditions, cancer, and heart failure are common forms of AI. The degree of anemia in ACD generally reflects the severity of the underlying disease.

Factors that contribute to anemia in critically ill patients include sepsis, frequent blood sampling, surgical blood loss, immune-mediated functional iron deficiency, decreased production of endogenous EPO, reduced RBC life span, and active bleeding, especially in the GI tract. A combination of these factors often exists, creating a rapid anemic state over days. Additional comorbid factors include coagulopathies and nutritional deficits such as poor oral intake and altered absorption of vitamins and minerals, including iron, vitamin B_{12}, and folate.[54] Deleterious effects of anemia include an increased risk of cardiac-related morbidity and mortality, especially for patients with known cardiovascular disease. Persistent tissue hypoxia can result in cerebral ischemia, myocardial ischemia, multiple organ deterioration, lactic acidosis, and death. The consequences of anemia in critically ill patients may be enhanced because of the increased metabolic demands of critical illness. Weaning anemic patients from mechanical ventilation may be more difficult, as low Hg has been identified as a potential risk factor for poor outcomes.[55,56] This is likely due to Hg's critical role in oxygen delivery; low Hg has been associated with increased work of breathing and cardiac output.[57–59]

Pathophysiology

AI is a hypoproliferative response to stimulation of the cellular immune system by various underlying disease processes. The pathogenesis of AI is multifactorial and is characterized by a blunted EPO response to anemia, an impaired proliferation of erythroid progenitor cells, and a disturbance of iron homeostasis. Increased iron uptake and retention occur within cells. The RBCs have a shortened life span, and the bone marrow's capacity to respond to EPO is inadequate to maintain normal Hb concentration. The cause of this defect is uncertain but related to impaired release of iron from bone marrow cells. Iron availability to erythroid progenitor cells is therefore limited. Various cytokines, such as interleukin-1, interferon-γ, interleukin-6, and tumor necrosis factor released during illness, may inhibit the production or action of EPO or the production of RBCs.[60] These cytokines also upregulate hepcidin, a small peptide that regulates iron availability. Increased hepcidin inhibits iron absorption from the gastrointestinal tract and prevents release from macrophages which are elevated during inflammation. Inflammation also increases the uptake of iron by macrophages reducing free iron for erythropoiesis.[60,61]

Laboratory Findings

ACD tends to be a mild (Hb greater than 9.5 g/dL [95 g/L; 5.90 mmol/L]) or moderate (Hb greater than 8 g/dL [80 g/L; 4.97 mmol/L]) anemia.[60] No definitive test can confirm the diagnosis of AI. The clinician should maintain a high index of suspicion for any patient with a chronic inflammatory or neoplastic disease. AI may coexist with IDA and folic acid deficiency because many patients with these conditions have poor dietary intake. Examination of the bone marrow, although not routinely performed, reveals an abundance of iron, suggesting that the release mechanism for iron is the central defect. Patients with AI usually have a decreased serum iron level, but unlike patients with IDA, their TIBC is decreased and their serum ferritin level is normal or increased. Ferritin is an acute phase reactant and is often elevated during inflammation, helping to delineate AI from IDA. Transferrin saturation is typically decreased. AI usually is normocytic and normochromic with mildly depressed Hb. Patients with concurrent AI and IDA usually have microcytes and a more severe anemia. Table 122-3 shows lab values seen in AI and IDA. Erythrocyte survival may be reduced for patients with AI, but a compensatory erythropoietic response does not occur. A low reticulocyte count indicates underproduction of RBCs.[60] As discussed in the IDA section, hepcidin levels are not routinely used for diagnosis but would likely be elevated in a patient with ACD.[62]

TABLE 122-3

Laboratory Value Differences Between Anemia of Inflammation and Iron-Deficiency Anemia

	Anemia of Inflammation	Iron-Deficiency Anemia
Iron	↓	↓
Transferrin	↓ or NL	↑
Transferrin saturation	↓	↓
Ferritin	↑ or NL	↓
Soluble transferrin receptor	NL	↑

NL, Normal limits.

Treatment

Treatment of AI depends on the underlying etiology. Resolution of the underlying condition may prompt recovery from anemia. Guidelines exist for management of anemia in patients with cancer or chronic kidney disease. Although the goals of therapy should include treating the underlying disorder and correcting reversible causes of anemia, accomplishment of these goals may not be feasible nor completely reverse hematologic and physiologic abnormalities. If AI is mild and does not affect the patient's quality of life or progression of other disease states, additional therapy may not be needed.

Iron supplementation is effective only if iron deficiency is present and should not be utilized for AI in its absence. During inflammation, oral or parenteral iron therapy may not be as effective. Absorption is impaired because of downregulation of ferroportin and iron diversion mediated by cytokines.[60] Because iron is a required nutrient for proliferating microorganisms, supplementation may also theoretically increase the risk of infections. Therefore, iron therapy should be reserved for patients with an established iron deficiency.[60]

ESAs have been used to stimulate erythropoiesis for patients with symptomatic AI since a relative EPO deficiency exists in comparison to the degree of anemia. Similar to endogenous EPO, response to exogenous ESA may be blunted in AI. Two agents are available: recombinant epoetin alfa and recombinant darbepoetin alfa. Although both agents share the same mechanism of action, darbepoetin alfa has a longer half-life and can be administered less frequently. ESAs are FDA approved for AI due to chronic kidney disease and HIV infection, as well as anemia due to malignancy, but are sometimes used off label for AI due to other underlying causes. The initial dosages of epoetin alfa and darbepoetin alfa are 50 to 100 Units/kg three times per week and 0.45 µg/kg once weekly, respectively. Response to ESAs varies depending on dose and cause of the anemia. Higher doses may be required to overcome hyporesponsiveness. Since ESAs are more effective when the marrow has an adequate supply of iron, cobalamin, and folic acid, these agents should be used in combination with iron therapy.

Iron deficiency can occur in patients treated with ESAs, so close monitoring of iron levels is necessary. Some patients develop “functional” iron deficiency, in which the iron stores are normal but the supply of iron to the erythroid marrow is less than necessary to support the demand for RBC production. Therefore, many practitioners routinely supplement ESA therapy with oral or IV iron therapy to maintain a serum ferritin ≥100 ng/mL (mcg/L; 225 pmol/L) or serum transferrin saturation (TSAT) ≥ 20%. Potential toxicities of exogenous ESA administration include increases in blood pressure, nausea, headache, fever, bone pain, and fatigue. Less-common adverse drug reactions include seizures, thrombotic events, and allergic reactions such as rashes and local reactions at the injection site. Tumor progression with these agents can also occur and is discussed in Chapter 150. Further discussion of dosing guidelines and potential adverse outcomes of ESA treatment in populations for which treatment is FDA approved are discussed in Chapters 63 and 150. If ESAs are used, the practitioner must monitor to ensure the patient’s Hb does not exceed 12 g/dL (120 g/L; 7.45 mmol/L) with treatment or that Hb does not rise greater than 1 g/dL (10 g/L; 0.62 mmol/L) every 2 weeks since both of these events have been associated with increased mortality and cardiovascular events.[63] Continued monitoring of Hb should be considered every 2 to 4 weeks thereafter. If no rise in Hb is seen after 8 weeks of optimal therapy, the patient should be considered EAS nonresponsive and therapy may be discontinued.

Transfusions of packed red blood cells are effective but should be limited to situations in which oxygen transport is inadequate due to concomitant medical problems and symptomatic patients with insufficient time to respond to other methods. RBC transfusions should be strongly considered for severe AI with complications involving bleeding. Liberal use of transfusions to correct anemia in critical illness can result in adverse patient outcomes.[53] Transfusion risks may include transmission of blood-borne infections, development of autoantibodies, transfusion reactions, and iron overload. Transfusions begin to be considered in most situations for those with severe anemia (Hb less than 7-8 g/dL [70-80 g/L; 4.34-4.97 mmol/L]).[64]

Critically ill patients require the necessary substrates of iron, folic acid, and vitamin B_{12} for RBC production. Parenteral iron is generally preferred in this population because patients often are undergoing enteral therapy or because of concerns regarding inadequate iron absorption. The disadvantage of parenteral therapy is the theoretical risk of infection, hypersensitivity reactions, including anaphylaxis, and hypotension during infusion.

ESAs have been used to treat the anemia of critical illness, but they are not FDA approved for this indication. In critically ill patients, the use of ESAs did not significantly reduce mortality or length of ICU stay.[65] The few randomized controlled trials which evaluated ESAs in this patient population did not consistently show a decrease in transfusion requirements in ESA-treated patients.[66] Additionally, their use is often limited by the rapid progression of anemia in this setting and the increased risk of thrombotic events with their use. Further investigation is necessary to determine the effectiveness of ESAs in critically ill patients.

Many critically ill patients receive RBC transfusions despite the inherent risks associated with transfusions. Stored RBCs may not function as well as endogenous blood. Although RBC transfusions may increase oxygen delivery to tissues, cellular oxygen may not increase.[67] Transfusion practices in ICUs vary, and clinicians use different Hb concentrations as thresholds for administering transfusions. The decision to use transfusions must consider the risks, including transmission of infections; volume overload, especially for patients with renal or heart failure; iron overload; and immune-mediated reactions such as febrile reactions, hemolysis, and anaphylaxis. The clinician also must consider administrative, logistic, and economic factors, including the shortage of blood supplies.

The recognition of hepcidin in the regulation of iron homeostasis and its role in ACD has led to interest in new agents targeted at hepcidin.

Mechanisms for these novel agents include inhibition of hepcidin production, circulating hepcidin, or hepcidin-inducing cytokines, including interleukin-6.

Prolyl hydroxylases have become potential targets for AI because they regulate hypoxia-inducible factors, which increase endogenous EPO formation and iron delivery. Prolyl hydroxylase inhibitors are in clinical trials to treat anemia in patients on hemodialysis.

ANEMIA IN OLDER ADULTS

Epidemiology

⑦ Anemia is one of the most common clinical problems observed in older adults, with about 20% of people aged 85 years and older affected.[68] Older patients with the highest incidence of anemia are those who are hospitalized, followed by residents of nursing homes and other institutions, with an estimated rate of 31% to 40%.[69] Although anemia is common in older adults, it should not be regarded as an inevitable outcome of aging. The body's set point of Hb does not fall with age. An underlying cause can be identified in about two-thirds of older patients. Undiagnosed and untreated anemia has been associated with adverse outcomes, including all-cause hospitalization, hospitalization secondary to cardiovascular disease, and all-cause mortality.[70] Anemia is an independent predictor of death and major clinical adverse events in older adults with stable symptomatic coronary artery disease.[71] Anemia can exacerbate neurologic and cognitive conditions and can adversely influence quality of life and physical performance in older adults.[72] Anemia may be an indication of serious diseases such as cancer.

Pathophysiology

Aging is associated with a progressive reduction in hematopoietic reserve, which increases the risk of anemia in times of hematopoietic stress.[73] Dysregulation of proinflammatory cytokines, most notably interleukin-6, may inhibit EPO production or interact with EPO receptors.[74] Although Hb levels may remain normal, the diminished marrow reserve leaves older adults more susceptible to other causes of anemia. Renal insufficiency, which also is common in older adults, may reduce the ability of the kidneys to produce EPO. Older patients often have a normal creatinine level but a diminished glomerular filtration rate. Myelodysplastic syndromes are another common cause of anemia in older adults, but most anemia cases in older adults are multifactorial.

Etiology

In the acute care setting, the most common causes of anemia in older adults are chronic disease (35%), unexplained (17%), and iron deficiency (15%), whereas in community-based outpatient clinics, the most common causes are unexplained (36%), infection (23%), and chronic disease (17%).[75] Another common problem in older adults is vitamin B_{12} deficiency. The most common causes of clinically overt vitamin B_{12} deficiency are food or cobalamin malabsorption (more than 60% of cases) and pernicious anemia (15%-20% of cases).[76]

One often overlooked major factor that may contribute to anemia in the older population is nutritional status. Cognitive and functional impairments in the older population may create barriers for patients to obtain and prepare a nutritious diet. Nutritional deficiencies that are not severe enough to affect the hematopoietic system in the younger population may contribute to anemia in older adults. Edentulous or older adults who may be too ill to prepare their meals are at risk for nutritional folate deficiency. Risk factors for inadequate folate intake in older adults include low caloric intake, inadequate consumption of fortified cereals, and failure to take a vitamin/mineral supplement. However, unlike vitamin B_{12} levels, folate levels often increase rather than decline with age. High folic acid intake can occur if older adults regularly take a supplement and consume fortified cereals.[77,78]

Bleeding with resultant iron deficiency in older adults may be due to carcinoma, peptic ulcer, atrophic gastritis, drug-induced gastritis, postmenopausal vaginal bleeding, or bleeding hemorrhoids. Older women have a much lower incidence of IDA compared with younger, menstruating women. Until proven otherwise, iron deficiency in older adults should be considered a sign of chronic blood loss. Steps should be taken to rule out bleeding, especially from the GI or female reproductive tract. AI is more common in older adults, as diseases that contribute to AI such as cancer, infection, and rheumatoid arthritis are more prevalent in this population.

Laboratory Findings

For practical purposes, it is best to use usual adult reference values and WHO criteria for laboratory tests in older adults. Anemia in older adults usually is normocytic and mild, with Hb values ranging between 10 and 12 g/dL (100-120 g/L; 6.21-7.45 mmol/L) in most anemic patients.[68] Evaluation of an older patient should be similar to strategies described previously for younger adults, perhaps with more emphasis on identifying occult blood loss and vitamin B_{12} deficiency. Vitamin B_{12} deficiency may be present even when plasma levels of vitamin B_{12} are within the normal range, but elevated MMA levels will reveal the deficiency. A refractory macrocytic anemia in older adults should raise suspicion of a myelodysplastic syndrome.

Treatment

Treatment of anemia in older adults is the same as that described for each type of anemia previously discussed in this chapter. With IDA, it is essential to treat the underlying cause, if known (ie, bleeding), and administer iron supplementation. Lower doses of iron supplementation are often recommended in older adults (eg, 325 mg of ferrous sulfate once daily or every other day) to decrease the incidence of GI adverse effects, which can lead to additional morbidity and poor adherence. Vitamin B_{12} can be repleted orally or parenterally. The dose for oral therapy is 1,000 to 2,000 μg daily depending on anemia severity and has been shown to be as effective as intramuscular injections. As with oral iron therapy, reticulocytosis often occurs within a week of Vitamin B_{12} therapy. Folate deficiency is treated with folic acid supplementation at 1 mg daily. The goal of treatment of AI is resolution of the underlying cause, although curing the underlying chronic illness in older adults can be difficult. Routine treatment with ESAs is not standard of care for AI in older adults.

ANEMIA IN PEDIATRIC POPULATIONS

Epidemiology

⑧ Globally, anemia is a significant cause of morbidity and mortality in pediatrics with an incidence as high as 47% in pre-school aged children and the highest concentration of patients found in Africa and Southeast Asia.[79] In the United States, the WHO reported the incidence of anemia in the pediatric population as 6% in 2011.[80] IDA accounts for the most cases of anemia in children and the prevalence of iron deficiency is reported to be as high as 20% in low-income families, likely due to diet.[81] IDA is a leading cause of infant mortality around the world.[82] Data from NHANES III indicated that 9% of children ages 12 to 36 months in the United States had iron deficiency and 3% had IDA.[83,84] Lack of a normal Hb at birth directly affects nonstorage iron and increases the risk of IDA in the first 3 to 6 months of life. An anemia of prematurity most commonly occurs 3 to 12 weeks after birth in infants younger than 32 weeks gestation and can spontaneously resolve by 3 to 6 months. Additional causes of anemia in pediatrics include “physiologic anemia” in newborns, G6PD deficiency, and thalassemia.

Etiology

The age of the child can yield some clues regarding the etiology of the anemia. From birth to 3 months, a “physiologic anemia” is the most common cause of anemia due to a decrease in erythropoiesis post-birth. At 3 to 6 months, hemoglobinopathy is more frequently encountered, as IDA is rare prior to 6 months of age. Iron deficiency becomes the most frequent etiology of anemia in toddler through adolescent years. The optimal amount of nutritional iron and folate required varies among individuals based on life-cycle stages. Two peak periods place children at risk of developing IDA. The first peak occurs during late infancy and early childhood, when children undergo rapid body growth, have low levels of dietary iron, and exhaust stores accumulated during gestation. The second peak occurs during adolescence, which is associated with rapid growth, poor diets, and onset of menses in girls. Some studies suggest that overweight children are at significantly higher risk for IDA. Proposed factors include genetic influences; physical inactivity, leading to decreased myoglobin breakdown and lower amounts of released iron into the blood; and inadequate diet with limited intake of iron-rich foods.[85]

Conditions in the newborn period that can lead to IDA include prematurity, low iron intake, and insufficient maternal iron consumption, particularly during the third trimester of pregnancy when 60% to 80% of fetal iron storage occurs. However, there is insufficient data to suggest that treatment of IDA in pregnant women will prevent IDA in newborns. Premature infants are at increased risk for IDA because of their smaller total blood volume, increased blood loss through phlebotomy, and poor GI absorption. Factors leading to unbalanced iron metabolism in infants include insufficient iron intake, early introduction of cow’s milk, intolerance of cow’s milk, medications, and malabsorption. Dietary deficiency of iron in the first 6 to 12 months of life is less common today because of the increased use of iron supplementation during breast-feeding and use of iron-fortified formulas. Iron deficiency becomes more common when children change to regular diets.

When screening for iron deficiency in young children, a careful dietary history can help identify children at risk. High iron needs and the tendency to eat fewer iron-containing foods contribute to the etiology of iron deficiency during adolescence.

Other causes of microcytic anemia include thalassemia, lead poisoning, and sideroblastic anemia. Normocytic anemias in children include infection with human parvovirus B19 and glucose-6-phosphate dehydrogenase (G6PD) deficiency. In the setting of G6PD deficiency, a thorough review of potential drug and toxin exposure around the onset of anemia will be helpful to determine an offending agent. Macrocytic anemias are caused by deficiencies in vitamin B_{12} and folate, chronic liver disease, hypothyroidism, and myelodysplastic disorders. Folic acid deficiency usually is due to inadequate dietary intake, but human milk and cow's milk provide adequate sources. Vitamin B_{12} deficiency due to nutritional reasons is rare but may occur due to congenital pernicious anemia.

Pathophysiology

In contrast to anemias in adults, which tend to be manifestations of a broader underlying pathology, anemias in the pediatric population are more often due to a primary hematologic abnormality. In newborn infants, "physiologic anemia" is often due to reduced EPO production.[86] Erythropoiesis also decreases during this time as a result of increased tissue oxygenation.

Hemoglobinopathy is often suspected in infants with anemia between the ages of 3 to 6 months because IDA is rare during this period. Potential causes include sickle cell anemia, thalassemia, and G6PD deficiency. Thalassemia is an inherited condition in which the Hgb structure is compromised leading to anemia of various degrees based on the subtype of thalassemia. This condition is most frequently seen in patients of Mediterranean and Southeast Asian heritage.[81] G6PD deficiency is an X-linked disorder most frequently seen in patients of Asian, Mediterranean, and African descent.[87] The lack of this enzyme reduces the RBC's protection against oxidative injury by limiting the glutathione available. Glutathione in RBCs rapidly inactivates oxidants preventing cellular injury. G6PD is an important enzyme in the formation of glutathione and a deficiency in this enzyme ultimately leads to hemolysis and anemia after exposure to an oxidant, such as dapsone, primaquine, or fava beans.

IDA should be suspected in microcytic anemia of children after 6 months of age. The amount of iron present at birth depends on gestational length and weight. Iron stores from birth are mostly depleted by 6 months of age. The addition of iron supplements and iron-enriched foods is important to maintain iron levels and prevent the development of IDA.

Laboratory Findings

When evaluating laboratory values for pediatric patients, the clinician must use age- and sex-adjusted norms. It is important to know that many blood samples are capillary samples, such as heel or finger sticks, which may have slightly different results than venous samples. The USPSTF has concluded that evidence is insufficient to recommend for or against routine screening for IDA in asymptomatic low-risk children aged 6 to 12 months. Hb is a sensitive test for iron deficiency, but it has low specificity in childhood anemias. If an abnormality is found, a CBC should be ordered to evaluate MCV and determine whether the anemia is microcytic, normocytic, or macrocytic. A peripheral blood smear and reticulocyte count also may be helpful. The peripheral blood smear can indicate the etiology based on RBC morphology, and the reticulocyte count helps differentiate between decreased RBC production and increased RBC destruction or loss. Other laboratory tests include serum iron, ferritin, TIBC, and transferrin saturation. Laboratory markers of hemolysis, including increased bilirubin, lactate dehydrogenase, and decreased haptoglobin, can identify hemolytic anemias, including G6PD deficiency and thalassemia. A G6PD deficiency screening test may be indicated if hemolysis is present. Mild hereditary anemias may produce a mild hypochromic microcytic anemia that can be confused with IDAs. The RDW may be high with iron deficiency and is more likely to be normal with thalassemia. Laboratory features of anemia of prematurity include normocytic normochromic cells, low reticulocyte count, low serum EPO concentrations, and decreased RBC precursors in bone marrow. Laboratory diagnosis of vitamin B_{12} and folate deficiency in children is similar to that of adults.

Treatment

Primary prevention of IDA in infants, children, and adolescents is the most appropriate goal because delays in mental and motor development are potentially irreversible. In 2015, the USPSTF published revised recommendations to screen and supplement iron deficiency in the United States, focusing on children and pregnant women. They concluded that the current evidence is insufficient to evaluate the benefits and harms of routine screening in asymptomatic children ages 6 to 24 months and routine use of iron supplementation in pregnant women to improve fetal outcomes.[88] Screening should be restricted to high risk children, including those with poor growth and insufficient iron intake. Routine iron supplementation for exclusively breastfed infants at 1 mg/kg/day is recommended by the American Academy of Pediatrics (AAP) beginning at 4 months until appropriate iron-containing foods are introduced. Fair evidence was found that iron supplementation (eg, iron-fortified formula or iron supplements) improves neurodevelopmental outcomes in children at risk for IDA. Due to the widespread use of iron-enriched formula, additional supplementation is rarely necessary in formula-fed infants.[80]

Interventions likely to prevent anemia include diverse foods with bioavailable forms of iron, food fortification for infants and children, and individual supplementation. Routine screening for iron deficiency in nonpregnant adolescents is recommended only for those with risk factors, which include vegetarian diets, malnutrition, low body weight, chronic illness, or history of heavy menstrual blood loss.

For infants aged 9 to 12 months with a mild microcytic anemia, the most cost-effective treatment is a therapeutic trial of iron. Fe^{2+} sulfate at a dose of 3 to 6 mg/kg/day of elemental iron divided once or twice daily between meals for 4 weeks is recommended. In children who respond, iron should be continued for 2 more months to replace storage iron pools, along with dietary intervention and patient education.[89] Liquid iron preparations can occasionally stain teeth. Kids should be advised to brush teeth or rinse out their mouth after administration. Parenteral iron therapy has a limited role and is rarely necessary.

For the macrocytic anemias in children, folate can be administered at a dose of 1 mg daily. However, vitamin B_{12} deficiency due to congenital pernicious anemia requires lifelong vitamin B_{12} supplementation. Dose and frequency should be titrated according to clinical response and laboratory values. No data regarding the use of oral vitamin B_{12} supplementation in children is available.

Treatment of normocytic anemias is based on underlying cause.

EVALUATION OF THERAPEUTIC OUTCOMES

For IDA, a positive response to a trial of oral iron therapy is characterized by modest reticulocytosis in days, with an increase in Hb starting after about 2 weeks with continued rapid rise in Hb. As the Hb level approaches normal, the rate of increase slows progressively. Hb should reach a normal level after about 2 months of therapy and often sooner.[12] If the patient does not develop reticulocytosis, reevaluation of the diagnosis or iron replacement therapy is necessary. Iron therapy should continue for a period sufficient for complete restoration of iron stores. Serum ferritin concentrations should return to the normal range prior to discontinuation of iron. The time interval required to accomplish this goal varies, although at least 6 to 12 months of therapy usually is warranted.

When large amounts of parenteral iron are administered, by either total dose infusion or multiple intramuscular or IV doses, the patient's iron status should be closely monitored. Patients receiving regular IV iron should be monitored for clinical or laboratory evidence of iron toxicity or overload. Iron overload may be indicated by abnormal hepatic function tests, serum ferritin greater than 800 ng/mL (800 μg/L [1,800 pmol/L]), or transferrin saturation greater than 50%. Serum ferritin and transferrin saturation should be measured in the first week after larger IV iron doses. Hb and Hct should be measured weekly, and serum iron and ferritin levels should be measured at least monthly.

Most patients with vitamin B_{12}–deficiency anemia respond rapidly to vitamin B_{12} therapy. The typical patient will experience improved strength and well-being within a few days of treatment initiation. Reticulocytosis is evident in 3 to 5 days. Hb begins to rise after the first week and should normalize in 1 to 2 months.[90] CBC and serum cobalamin levels usually are drawn 1 to 2 months after initiation of therapy and 3 to 6 months thereafter for surveillance monitoring. Homocysteine and MMA levels can be repeated 2 to 3 months after initiation of replacement therapy to evaluate for normalization of levels, although levels begin to decrease in 1 to 2 weeks. Neuropsychiatric signs and symptoms can be reversible if treated early. If permanent neurologic damage has resulted, progression should cease with replacement therapy. Slow response to therapy or failure to observe normalization of laboratory results may suggest the presence of an additional abnormality such as iron deficiency, thalassemia trait, infection, malignancy, nonadherence, or misdiagnosis.

In folic acid deficiency anemia, symptomatic improvement, as evidenced by increased alertness and appetite, often occurs early during treatment. Reticulocytosis begins in the first week. Hct begins to rise within 2 weeks and should reach normal levels within 2 months. MCV initially increases because of an increase in reticulocytes but gradually decreases to normal.

One of the earliest responses with ESA use is an increased blood reticulocyte count, which usually occurs in the first few days. Baseline iron status should be checked before and during treatment, as many patients receiving ESAs require supplemental iron therapy. The optimal form and schedule of iron supplementation are not known. Hb levels should be monitored twice a week until stabilized. Hb should also be monitored twice weekly for 2 to 6 weeks after a dose adjustment.[54] A fall in Hb during ESA therapy may indicate a need for iron supplementation or signal occult blood loss. Baseline and periodic monitoring of iron, TIBC, transferrin saturation, or ferritin levels may be useful in optimizing iron repletion and limiting the need for ESAs. Patients who do not respond to 8 weeks of optimal dosage should not continue taking ESAs. Target Hb levels should be 11 to 12 g/dL (110-120 g/L; 6.83-7.45 mmol/L). Cost is an issue with ESA therapy. Therefore, drug cost must be weighed against the effects on transfusions and hospitalizations.

In older adults, responses and treatment monitoring are similar as that described for the general adult population. If the reticulocyte count rises but the anemia does not improve, inadequate absorption of iron or continued blood loss should be suspected. As with any form of anemia, symptomatic improvement should be evident shortly after starting therapy and Hb/Hct should begin to rise within a few weeks of initiating therapy. A key component of symptom assessment among older adults is the functional domain. Patients should be asked about changes in self-care abilities, mobility, and stamina.

Therapeutic outcomes are assessed in children by monitoring Hb, Hct, and RBC indices 4 to 8 weeks after initiation of iron therapy. For premature infants, Hb or Hct should be monitored weekly.

CONCLUSION

Anemia affects many patients across the lifespan, impacting morbidity and mortality. The causes of anemia can vary and includes genetic disorders, nutritional deficiencies, chronic disease, and acute illness. Identification of the correct cause of anemia through lab assessment is key to selecting the appropriate treatment and monitoring plan. While anemia can sometimes be a symptom or complication of another disease or deficiency, it is important for clinicians to understand the disease and how to treat it.

ABBREVIATIONS

ACD	anemia of chronic disease

SELF-ASSESSMENT QUESTIONS

1. Classification of anemias is *not* based on:

   A. Pathophysiology

   B. Morphology

   C. RBC indices

   D. Etiology

2. Stimulation of erythropoiesis

   A. Is due to a decrease in tissue oxygen levels

   B. Results in decreased release of reticulocytes from the bone marrow

   C. Is due to an increase in tissue oxygen levels

   D. Is due to rising levels of erythropoietin from the liver

3. Serum iron levels in iron deficiency anemia:

   A. May remain within the normal range

   B. May have a 20% to 30% diurnal variation

   C. Reflect the concentration of iron bound to transferrin

   D. All of the above

4. Iron is *best* absorbed:

   A. From vegetables

   B. With concurrent tea administration

   C. In the ferrous form

   D. In an alkaline environment

5. Which one of the following is *correct* regarding therapeutic doses of oral iron?

   A. The enteric formulation results in increased iron absorption.

   B. Reticulocytosis occurs within 7 days after initiation of therapy.

   C. Iron therapy should be continued for 1 week of therapy and then discontinued.

   D. Oral iron should preferably be administered in a single dose with food.

6. Which of the following is an appropriate lab to help differentiate between vitamin B_{12} deficiency and folate deficiency in an anemic patient?

   A. Homocysteine

   B. Hemoglobin

   C. MMA (methylmalonic acid)

   D. MCV (mean cell volume)

7. Parenteral iron therapy:

   A. Is best administered IV rather than IM

   B. Should be given initially as a loading dose

   C. Requires concurrent erythropoietin therapy

D. Should be given if Hgb does not increase within 7 days of oral iron therapy initiation

8. Which one of the following is *correct* regarding the treatment of vitamin B_{12} deficiency?

    A. Neurological manifestations are reversible regardless of the length of vitamin B_{12} deficiency.

    B. Vitamin B_{12} tablets that are available over the counter can be used in many cases to treat deficiency.

    C. Vitamin B_{12} given via nasal spray can be used when neurological symptoms are present.

    D. Oral replacement therapy cannot be utilized if a patient lacks intrinsic factor.

9. Which one of the following is *correct* regarding folic acid deficiency anemia?

    A. Folate is synthesized in the human body.

    B. Ingestion of alcohol interferes with the absorption of folate.

    C. Folic acid deficiency anemia results in neurologic manifestations.

    D. Supplementation with folic acid 1 μg daily will replenish folate stores.

    E. Serum concentrations of methylmalonic acid and homocysteine are elevated.

10. Patients with anemia of chronic disease

    A. Have decreased levels of iron in the bone marrow

    B. Can be clearly identified from a review of laboratory values

    C. May have a normal ferritin

    D. Respond best to oral iron therapy during inflammation

11. Which of the following statements is true regarding production/maturation of RBCs?

    A. The main site of production of RBCs is the spleen.

    B. As oxygen levels start to decrease, less erythropoietin is produced.

    C. A pluripotent stem cell always becomes a red blood cell.

    D. The bone marrow releases reticulocytes into the circulation.

12. Which one of the following statements is *incorrect* regarding adherence to anemia therapy?

    A. Patients may cease taking oral iron therapy due to concerns regarding the development of dark stools.

    B. Oral iron therapy may result in diarrhea or constipation.

    C. Patients may be nonadherent to parenteral routes of vitamin B_{12} supplementation due to fear of injections.

    D. Combination of iron products containing stool softeners are beneficial to avoid constipation.

13. Which of the following medications could affect how well iron is absorbed?

    A. Warfarin

B. Methotrexate

C. Omeprazole

D. Metformin

14. Which of the following gives you the best estimation of total iron stores in the body?

A. Serum iron

B. Ferritin

C. Total iron binding capacity

D. Transferring saturation

15. Which of the following statements is TRUE regarding production/maturation of red blood cells?

A. The main site of production of red blood cells is the spleen.

B. A pluripotent stem cell always becomes a red blood cell.

C. The bone marrow releases reticulocytes in the circulation.

D. Erythropoietin acts mainly on the kidneys to produce red blood cells.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** Anemia classification can be done through various methods. However, red blood cell indices do not always distinguish between different types of anemias. For example, in vitamin B_{12} deficiency and folic acid deficiency anemia, the MCV can be elevated. These indices can give clues about types of anemias, but are not definitive.

2. **A.** Erythropoiesis increases when there is a drop in tissue oxygen levels. When this happens, the kidney produces more erythropoietin that stimulates the bone marrow to release more reticulocytes.

3. **D.** Initially, serum iron levels may not drop below normal range, despite the patient having iron deficiency anemia, due to the iron stores in the body. There is variation in this level depending on the time of the day and this level also represents iron is bound to transferrin.

4. **C.** There are several things that decrease oral iron absorption. Heme iron is better absorbed and this type of iron comes more from meats and not vegetables. Tea and wine due to the tannins decrease absorption. An acidic environment in the stomach increases absorption. Medications that suppress acid and make it more alkaline decrease absorption.

5. **B.** The recommended oral dose can be around 60- to 65-mg elemental iron daily, some evidence may suggest a lower dose or this amount several times per week. Food decreases absorption of iron. Enteric formulations do not allow iron to be released in the stomach. Lastly, iron therapy should be continued for several months following labs and symptoms returning to normal.

6. **C.** MCV, homocysteine, and hemoglobin will be decreased in both folate deficiency and vitamin B_{12} deficiency. Vitamin B_{12} is required for an enzymatic reaction with MMA, a deficiency in B_{12} results in increased levels. Folate is not involved in this reaction.

7. **A.** Intramuscular iron therapy results in adverse skin reactions and staining, the preferred route is IV. Loading doses are typically not used with parenteral iron and the rate at which it is given is important to avoid infusion reactions. Erythropoietin is not required for IV iron therapy and hemoglobin will likely take longer to rise than 1 week.

8. **B.** Vitamin B_{12} replacement with 1,000 mg can be done with a nonprescription formulation found in almost all pharmacies. If neurological

symptoms are present, intramuscular is preferred prior to oral replacement. If neurological symptoms from B_{12} deficiency are present for an extended period of time they can become irreversible. There is absorption of B_{12} via passive diffusion that does not rely on intrinsic factor, which allows for oral replacement in those patients lacking it.

9. **B.** Heavy alcohol use decreases the absorption of folate. Supplementation is necessary with oral folic acid 1 mg daily, in most cases, as it is not synthesized by the body. A distinguishing feature of folate deficiency from B_{12} is that in folate deficiency MMA is not elevated and there are no neurological complications from deficiency.
10. **C.** Ferritin is an acute-phase reactant during inflammation. This level may be elevated in some anemia of chronic disease patients due to the ongoing inflammation. Even though this level is elevated, the patient may still be functionally iron deficient. Iron can be sequestered in the bone marrow during anemia of chronic disease and unavailable for use. These factors can make evaluation of lab parameters difficult in some patients.
11. **D.** A pluripotent stem cell can differentiate into several different types of cells, like red blood cells or white blood cells. Red blood cell production occurs mainly in the bone marrow, while destruction happens in the spleen. When oxygen levels drop in a normal patient, the kidney produces more erythropoietin to help the bone marrow produce and release more reticulocytes.
12. **D.** Iron products can cause diarrhea or constipation in patients. Typically, if constipation is caused it does not respond as well to a stool softener and a stimulant laxative may be needed. A common adverse effect of oral iron therapy is dark, black stools. Fear of injections could limit one's ability to treat with parenteral vitamin B_{12}.
13. **C.** An acidic environment in the stomach helps iron to be best absorbed. Omeprazole can lower the acid in the stomach and can decrease iron absorption. Metformin affects vitamin B_{12} absorption. Methotrexate can interfere with folic acid absorption. Warfarin does not affect absorption of any of the vitamins/minerals discussed in this chapter.
14. **B.** Serum iron, transferrin saturation, and total iron binding capacity do not measure actual stores in the body, they reflect how much iron is in the blood. Ferritin measures iron stores.
15. **C.** Bone marrow is the primary site of red blood cell production and young red blood cells, reticulocytes are released from there into the circulation to further mature. The spleen is the main site of red blood cell destruction. A pluripotent stem cell can become other types of cells, not just a red blood cell. Erythropoietin does act on the kidney but its action on the bone marrow stimulates production of red blood cells.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 123: Coagulation Disorders

Heidi Trinkman; Timothy L. McCavit; Lauren Duran

KEY CONCEPTS

KEY CONCEPTS

① Hemophilia is an inherited bleeding disorder resulting from a congenital deficiency in factor VIII or IX.

② The goal of therapy for hemophilia is to prevent bleeding episodes and their resulting long-term complications and to arrest bleeding if it occurs.

③ Recombinant factor concentrates usually are the first-line treatment of hemophilia because they have the lowest risk of infection.

④ Inhibitor formation is the most significant treatment complication in hemophilia and is associated with significant morbidity and decreased quality of life.

⑤ Recombinant factor VIIa is effective for the treatment of acute bleeds in patients with hemophilia A or B who have developed inhibitors.

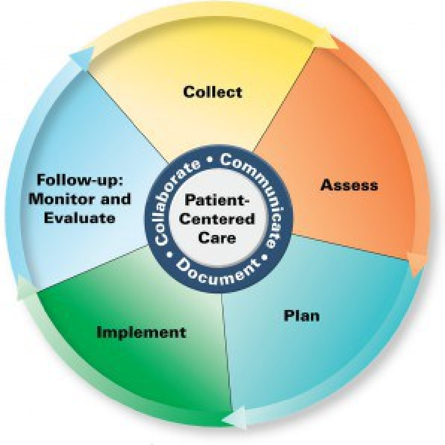
⑥ The goal of therapy for von Willebrand disease (vWD) is to increase von Willebrand factor (vWF) and factor VIII levels to prevent bleeding during surgery or arrest bleeding when it occurs.

⑦ vWF concentrates are the agents of choice for treatment of type 3 vWD and some type 2 vWD, and for serious bleeding in type 1 vWD.

⑧ Desmopressin acetate often is effective for the treatment of type 1 vWD. It also may be effective for the treatment of some forms of type 2 vWD in addition to mild-to-moderate hemophilia A.

PATIENT CARE PROCESS

Patient Care Process for Coagulation Disorders



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (age, sex, etc.)
- Patient medical history (including family history and bleeding history)
- Social history (level of activity, extracurricular activities)
- Medication list, especially aspirin, nonsteroidal anti-inflammatory drugs [NSAIDs], other antiplatelet medications and anticoagulants
- Labs—clotting factors

Assess

- Presence of active bleeding (see "Clinical Manifestations and Diagnosis" section and Table 123-1)
- Presence of common clinical manifestations in bleeding disorders (easy bruising, bleeding after surgery, mucocutaneous bleeding, prolonged menses, etc., and Table 123-1).
- Factor level and the need for prophylactic management

Plan*

- Determine drug therapy regimen (dose, route, frequency, and duration) (see Table 123-3 and "Treatment: Hemophilia" section)
- Monitoring parameters (signs/symptoms of bleeding, frequency of bleeding episodes)
- Patient education/counseling (control of bleeding episodes, administration of drug therapy, when to seek medical attention)
- Continued care at a Hemophilia Treatment Center (or comparable clinic with a comprehensive care team)

Implement

- Provide education and reinforcement of the treatment plan
- Improve adherence through motivational interviewing and open discussions about patient care and the treatment plan
- Schedule regular clinic appointments to assess adherence, bleeding episodes, and to tailor patient therapy

Follow-up: Monitor and Evaluate

- Control and resolution of bleeding signs and symptoms

- Number of bleeding episodes (improvement since beginning care, need for adjustment in the treatment plan)
- Factor level activity (tailor factor doses to patient-specific levels)
- Adherence to the treatment plan (prophylactic and as-needed therapy, seeking medical attention)

[*] *Collaborate with patients, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Create a Venn diagram to compare hemophilia A and B. Within the diagram, be sure to include pertinent disease state information such as clinical manifestations, incidence, and recommended treatment. List specific short- and long-acting products used in each type, as well as treatment modalities that may be common to both.

INTRODUCTION

The coagulation system is intricately balanced and designed to stop bleeding at the site of vascular injury through complex interactions between the vascular endothelium, platelets, procoagulant proteins, anticoagulant proteins, and fibrinolytic proteins. Hemostasis stops bleeding at the site of vascular injury through the formation of an impermeable platelet and fibrin plug. Three key mechanisms facilitate hemostasis including vascular constriction, primary platelet plug formation (primary hemostasis), and clot propagation through fibrin formation (secondary hemostasis). Derangements in this system can lead to either bleeding or thrombosis. Bleeding disorders are the result of a coagulation factor defect, a quantitative or qualitative platelet defect, or enhanced fibrinolytic activity.

COAGULATION FACTORS

Secondary hemostasis facilitates propagation and stabilization of the initial platelet plug formed in primary hemostasis through the formation of fibrin on the activated platelet surface. This step is initiated via the tissue factor pathway and is vital for adequate hemostasis. Coagulation factors circulate as inactive precursors (zymogens). Activation of these coagulation proteins leads to a cascading series of proteolytic reactions. At each step, a clotting factor undergoes limited proteolysis and becomes an active protease (designated by a lowercase “a,” as in Xa).

The coagulation factors can be divided into three groups based on biochemical properties: vitamin K–dependent factors (II, VII, IX, and X), contact activation factors (XI and XII, prekallikrein, and high-molecular-weight kininogen), and thrombin-sensitive factors (V, VIII, XIII, and fibrinogen). Biologic half-life and blood product source varies by coagulation factor.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The diagnosis of coagulation disorders is established from a detailed clinical history, physical examination, and laboratory test results. The clinical history should ascertain if there is a family history of bleeding or known bleeding disorders. Laboratory testing can distinguish bleeding disorders caused by defects in the coagulation pathways, fibrinolytic pathways, or alterations in the number or function of platelets. Table 123-1 describes common coagulation tests.

TABLE 123-1

Laboratory Procedures

Procedure	Identifies	Possible Cause of Abnormal Value	Clinical Manifestations

Prothrombin time (PT)	Factors I, II, V, VII, X	Newborn Vitamin K deficiency Inherited factor deficiencies[a] Warfarin therapy Liver disease Lupus anticoagulant (rare) Afibrinogenemia Dysfibrinogenemia	Bleeding following surgery, trauma, etc. Easy bruising
Activated partial thromboplastin time (aPTT)	Factors I, II, V, VIII, IX, X	Inherited factor deficiencies[a] Lupus anticoagulant Heparin therapy Liver disease Afibrinogenemia Dysfibrinogenemia	Joint and muscle bleeding Bleeding after surgery, trauma, etc.
	High-molecular-weight kininogen (HMWK), prekallikrein		No bleeding manifestations
	Factor XII		Increased incidence of thrombotic disease possible with severe factor XII deficiency
	Factor XI		Variable bleeding tendency Bleeding following surgery, trauma, etc.
Thrombin time (TT)	Fibrinogen Inhibitors of fibrin aggregation	Afibrinogenemia Dysfibrinogenemia Heparin therapy	Lifelong hemorrhagic disease Variable clinical symptoms from asymptomatic to either a bleeding diathesis or prothrombotic
Platelet count	Thrombocytopenia	Quantitative platelet disorder, type 2B von Willebrand disease, immune thrombocytopenia, other cause of thrombocytopenia	Mucocutaneous bleeding
Platelet function analyzer	Platelet function	Qualitative platelet defects, von Willebrand disease, antiplatelet therapy Also prolonged in anemia and thrombocytopenia[b]	Mucocutaneous bleeding

Platelet aggregation	Gold standard to assess platelet function	Qualitative platelet defects, antiplatelet medications	Mucocutaneous bleeding
Euglobulin clot lysis time (ECLT)	Fibrinolytic defect	A decreased ECLT indicates hyperfibrinolysis, which indicates an abnormality in the fibrinolytic pathway including plasminogen activator inhibitor 1 deficiency, α_2-plasminogen inhibitor deficiency Hypofibrinogenemia	Bleeding after trauma or surgical procedures especially in oral and urogenital areas

[a] Bleeding manifestations depend on factor levels.

[b] Insensitive to mild platelet defects and has fallen out of favor as a screening test

HEMOPHILIA

① Hemophilia is a bleeding disorder that results from a congenital deficiency in a plasma coagulation protein. Hemophilia A (classic hemophilia) is caused by a deficiency of factor VIII and hemophilia B (Christmas disease) is caused by a deficiency of factor IX. Hemophilia affects about 400,000 males worldwide.[1] The incidence of hemophilia A is about 1 in 5,000 male births and hemophilia B occurs in 1 in 30,000 male births.[2] Hemophilia A constitutes 80% to 85% of all patients with hemophilia with the other 15% to 20% being hemophilia B.[1] The incidence of hemophilia is not affected by race.

About one-third of patients with hemophilia have a negative family history, presumably representing a spontaneous mutation.[1] Both hemophilia A and hemophilia B are recessive X-linked diseases, which means that the defective gene is located on the X chromosome. The disease primarily affects only males while females are carriers. Since affected males have the abnormal allele on their X chromosome and no matching allele on their Y chromosome, their sons would be normal (assuming the mother is not a carrier) and their daughters would be obligatory carriers. Female carriers have one normal allele and, therefore, do not usually have a bleeding tendency, although female carriers have lower factor VIII levels than females who are not carriers.[3] Sons of a female carrier and a normal male have a 50% chance of having hemophilia and daughters have a 50% chance of being carriers. Thus, there is a “skipped generation” mode of inheritance in which the female carriers do not express the disease but can pass it on to the next male generation. Hemophilia has been observed in a small number of females. It can occur if both factor VIII and IX genes are defective or if a female patient has only one X chromosome as in Turner syndrome.[4]

In 1984, researchers isolated and cloned the human factor VIII gene. It is a large gene, consisting of 186 kilobases (kb).[5] More than 2,000 unique mutations in the factor VIII gene, including point mutations, deletions, and insertions, have been reported.[6] Deletions and nonsense mutations are often associated with the more severe forms of factor VIII deficiency because functional factor VIII is not produced. In 1993, researchers identified an inversion in the factor VIII gene at intron 22 that accounts for almost 30% to 45% of severe hemophilia A gene abnormalities.[1] That discovery has greatly simplified carrier detection and prenatal diagnosis in families with this gene mutation.

The factor IX gene, cloned and sequenced in 1982, consists of only 34 kb and is significantly smaller than the factor VIII gene.[5] Unlike the factor VIII gene in patients with severe hemophilia A, the factor IX gene in patients with hemophilia B has no predominant mutation. Direct gene mutation analysis is simpler in hemophilia B because of the smaller gene size, and to date more than 1,000 different mutations have been reported.[7] Most of these mutations are single base-pair substitutions. About 3% of factor IX gene mutations are deletions or complex rearrangements, and the presence of these mutations is associated with a severe phenotype.[1]

Hemophilia B Leyden is a rare variant in which factor IX levels initially are low but rise at puberty. The mechanism of this disorder is controversial. Some propose that the binding of the androgen receptor and other transcription factors are responsible. Other molecular mechanisms for age-related gene regulation have been discovered and implicated in factor IX Leyden.[8] Identification of this genotype is clinically important because it confers a better prognosis.

Clinical Presentation and Diagnosis

CLINICAL PRESENTATION: Hemophilia

Signs and Symptoms

- Ecchymoses (palpable/raised)
- Hemarthroses (especially knee, ankle, and elbow)
- Joint pain
- Joint swelling and erythema
- Decreased range of motion
- Muscle hemorrhage
- Swelling at the site of muscle bleeding
- Pain with motion of affected muscle
- Signs of nerve compression
- Significant anemia from an iliopsoas or thigh bleed
- Oral bleeding with dental extractions or trauma
- Hematuria
- Intracranial hemorrhage (spontaneous or following trauma)
- Excessive bleeding with surgery

Laboratory Testing

- Prolonged aPTT
- Decreased factor VIII or factor IX level
- Normal prothrombin time
- Normal platelet count
- Normal von Willebrand factor antigen and activity
- Normal bleeding time

The characteristic bleeding manifestations of hemophilia include palpable ecchymosis, bleeding into joint spaces (hemarthroses), muscle hemorrhages, and excessive bleeding after surgery or trauma. The severity of clinical bleeding generally correlates with the degree of deficiency of either factor VIII or factor IX. Factor VIII and factor IX activity levels are measured in units per milliliter, with 1 unit/mL representing 100% of the factor found in 1 mL of normal plasma.[2] Normal plasma levels range from 0.5 to 1.5 units/mL (50%-150%). Patients with less than 0.01 units/mL (1%) of either factor are classified as having severe hemophilia, those with between 0.01 and 0.05 units/mL (1%-5%) are moderate, and those with between 0.05 and 0.4 units/mL (5%-40%) have mild hemophilia.

Patients with severe disease experience frequent spontaneous hemorrhages, while those with moderate disease have excessive bleeding following mild trauma and rarely experience spontaneous hemarthroses. Patients with mild hemophilia may have few symptoms that their condition can be undetected for many years and they usually have excessive bleeding only after significant trauma or surgery. Disease severity does not always correlate with disease manifestations. Those with severe disease (<1% [0.01 units/mL] factor activity) may occasionally not display a severe phenotype, while some with milder forms of the disease may have more severe bleeding. Prolonged bleeding after circumcision is a common presenting sign. Most patients will have some manifestation of the disease sometime after their first year of life when they begin to walk and increase their risk of bleeding due to falling.[1]

The diagnosis of hemophilia should be considered in any male with unusual bleeding. A family history of bleeding is helpful in the diagnosis but is absent in up to 50% of patients with about one-third representing spontaneous mutations and the remaining secondary to unrecognized family history.[5] Brothers of patients with hemophilia should be screened; sisters should consider undergoing carrier testing. Laboratory testing in patients with hemophilia will usually reveal an isolated prolonged partial thromboplastin time and they will have a decreased factor VIII or factor IX level.

Patients with severe hemophilia A should be tested for the common factor VIII gene inversions. In patients with severe hemophilia A who lack an inversion mutation or in patients with moderate or mild hemophilia A, the gene can be sequenced to determine the exact mutation if needed. The exact mutation can determine carrier status but is not done routinely because it is very costly and does not change therapy. Techniques to determine the genetic mutation in patients with hemophilia B are similar, but no predominant mutation like the factor VIII inversion has been found. The smaller size of the factor IX gene facilitates direct DNA mutational analysis.[7]

Hemophilia can be diagnosed prenatally, if desired, by chorionic villus sampling in gestational weeks 9 to 14 or by amniocentesis after 15 to 17 weeks of gestation.[1,9] These are invasive procedures with a 0.5% to 1% chance for pregnancy loss so it is not routinely done.[9] A new noninvasive method uses cell-free fetal DNA in maternal circulation to determine the sex of the fetus; more invasive testing is required for a male fetus.[9] This method was used to successfully identify hemophilia mutations but is still experimental and requires further validation.[10]

Treatment: Hemophilia

② The comprehensive care of hemophilia requires an interprofessional team approach. The patient is best managed in specialized centers with trained personnel and appropriate laboratory, radiologic, and pharmaceutical services.[1] The healthcare team should include hematologists, orthopedic surgeons, nurses, physical therapists, dentists, genetic counselors, psychologists, pharmacists, case managers, and social workers who have experience in caring for patients with bleeding disorders. The goal for comprehensive hemophilia care is to prevent bleeding episodes and their long-term sequelae so that patients with hemophilia can live full, active, and productive lives.

Patients with hemophilia should receive routine immunizations, including immunization against hepatitis B. Hepatitis A vaccine is also recommended for patients with hemophilia because of the risk (albeit small) of transmitting the causative agent through factor concentrates. The administration of vaccines is preferred subcutaneously in patients with severe disease.[1,11] If intramuscular administration is required, the use of a small-gauge needle with cold compresses and pressure to the site can prevent excessive bleeding.

A few special considerations apply to the perinatal care of male infants of hemophilia carriers. Intracranial or extracranial hemorrhage occurs in 1% to 2% of newborns with hemophilia.[7] Vacuum extraction and forceps delivery increase the risk of cranial bleeding. Elective cesarean section does not prevent intracranial bleeding. The optimal mode of delivery or the use of prophylactic factor replacement in male infants of hemophilia carriers is controversial.[1] Circumcision should be postponed until a diagnosis of hemophilia is excluded. Factor levels can be assayed from cord blood samples or from peripheral venipuncture. Arterial puncture should be avoided because of the risk of hematoma formation. If an infant has hemophilia, many clinicians recommend a screening head ultrasound to rule out an intracranial hemorrhage prior to discharge from the nursery.[1,12]

Prophylaxis

The prevention of bleeding episodes and their resulting long-term complications is the mainstay of treatment for hemophilia. This can be accomplished through the regular administration of factor products or non-factor products to maintain hemostasis and prevent bleeding. It should begin early in life (before the age of 3 years old) to prevent musculoskeletal complications associated with joint or muscle bleeds. The goal of prophylaxis is to maintain a minimum factor activity or hemostasis level which would allow the patient to live a healthy and active life. Prophylaxis for patients with severe hemophilia is considered to be the standard of care recommended by the World Health Organization and the World Federation of Hemophilia (WFH).[1] Prophylaxis is sometimes required in patients with moderate hemophilia but is rarely used in patients with mild hemophilia.

Age at initiation of prophylaxis is a strong predictor of long-term clinical outcomes. Primary prophylaxis is started at a young age (usually before age 2 years), prior to the onset of joint bleeding.[13] Secondary prophylaxis begins after significant joint bleeding has already occurred.[13] In 2001, the Medical and Scientific Advisory Council of the National Hemophilia Foundation of the United States recommended primary prophylaxis beginning at age 1 to 2 years for children with severe hemophilia.

Prophylaxis Using Factor Replacement

Prophylactic factor replacement therapy is the regular intravenous administration of the deficient factor to maintain adequate activity levels to prevent bleeding. This effectively converts severe hemophilia into a milder form of the disease. The rationale for this approach is that patients with moderate hemophilia rarely experience spontaneous hemarthroses, and they have a much lower risk of chronic arthropathy. Many clinical trials proved the efficacy of a prophylactic approach in pediatric patients both in previously treated and untreated patients. The common finding is that prophylaxis prevented joint damage and decreased the frequency of joint and other hemorrhages.[13,14]

The dosing for prophylactic regimens varies considerably and no one regimen has been proven to be superior. Early on, patients with hemophilia A would be dosed on an every other day or three times a week regimen of standard half-life (SHL) factor VIII. For hemophilia B, the usual dosing of standard half-life factor IX would be twice weekly because of the intrinsically longer half-life.[1] The recent introduction of extended half-life factor products has made prophylaxis a more feasible approach (see Table 123-2). Patients with hemophilia A can now be dosed with an extended half-life product at 3- to 5-day intervals depending on their individual response.[14,15] Similarly, patients with hemophilia B can be dosed with an extended half-life product once weekly or every 10 to 14 days.[15] The extended half-life factor products allow for a much more ambitious dosing approach achieving higher activity levels in the mild and non-hemophilic range for substantial periods of time.[1]

Prophylactic factor replacement therapy comes with its own set of challenges. In addition to the paucity of standardized regimens, a significant challenge is the high cost of this approach. The cost to treat a patient with hemophilia A in the United States is about $300,000 per year.[16] Other issues to consider are the inconvenience to families and possible difficulties with adherence. Central venous lines may be necessary for frequent administration of factor concentrates, particularly in children younger than 2 years, who are at the age when primary prophylaxis is considered. Potential complications of central venous access include surgical risks, infection, and catheter-related deep-vein thrombosis.[1]

Prophylaxis with Nonfactor Products

While prophylaxis with factor products has been the mainstay of hemophilia treatment, the landscape is changing with the development of new therapeutic approaches and products for hemostasis. Non-factor replacement products for prophylaxis differ from the factor products in that they obtain hemostasis through unique mechanisms. This is an area of growing research. The only commercially available product for this purpose is emicizumab for hemophilia A. Emicizumab is a recombinant, humanized, bispecific monoclonal antibody that bridges activated factor IX and factor X, performing the function of the missing activated factor VIII in maintaining hemostasis in patients with hemophilia A. Due to its unique structure, the risk of developing neutralizing antibodies to the drug is low and it is not affected by the patient’s preexisting inhibitors (neutralizing antibodies) to factor VIII if present. Due to a prolonged half-life of 4 weeks, it can be administered in a single subcutaneous injection once weekly and in some cases every 2 to 4 weeks. The safety and efficacy of emicizumab has been demonstrated in children and adults with hemophilia A for prophylaxis therapy in the HAVEN 1-4 trials.[17,18]

In patients with inhibitors, emicizumab is much more effective than previously utilized prophylaxis modalities such as recombinant activated factor VII or activated prothrombin complex concentrates (aPCC). In non-inhibitor patients, emicizumab reduces the annual bleeding rate, or ABR even lower than some reported trials in patients receiving factor replacement prophylaxis. The subcutaneous administration of emicizumab is allowing prophylaxis to start even earlier in children 6 to 12 months of age without the need for indwelling central lines. It avoids the peaks and troughs associated with prophylactic factor replacement therapy and is much more convenient for patients and families potentially increasing adherence and thereby improved outcomes.[1]

With the success of emicizumab and the promise of future non-factor products on the way, the concepts and definitions of prophylaxis for hemophilia patients are shifting to be more inclusive of a wide variety of mechanisms of action and modalities of administration. The WFH is proposing a new definition based on outcomes rather than doses of products used or age of initiation. They propose the following as a modern definition of prophylaxis: the regular administration of a hemostatic agent/agents with the goal of preventing bleeding in people with hemophilia while allowing them to lead active lives and to achieve a quality of life comparable to a non-hemophilic individual.[1]

Hemophilia A

Therapy for hemophilia has undergone dramatic advances over the past few decades. Fifty years ago, the administration of fresh-frozen plasma was the only available treatment. The introduction of cryoprecipitate in the early 1960s allowed more specific therapy for hemophilia A.[19] Intermediate-purity factor VIII and IX plasma-derived concentrates became available in the 1970s.[19] Plasma-derived factor concentrates are made from the donations of thousands of people. Contamination of plasma pools with hepatitis B, hepatitis C, and the human immunodeficiency virus (HIV) during the late 1970s and early 1980s resulted in transmission to a large portion of patients with hemophilia. Since the mid-1980s, plasma-derived concentrates have been manufactured with a variety of virus-inactivating techniques, including dry heat, pasteurization, and treatment with chemicals (eg, solvent detergent mixtures).[5] Since 1986, no transmission of HIV through factor concentrates to patients with hemophilia in the United States has been reported.[5] Protein purification techniques, introduced in the 1990s, led to the production of high-purity plasma-derived concentrates with increased amounts of factor VIII or factor IX relative to the product’s total protein content. Recombinant factor VIII and then factor IX also became available in the 1990s.[19] Significant improvements have been made with recombinant products in limiting the risk of infectious transmission from albumin used to stabilize some of the products. Like plasma-derived products, these products use viral inactivation steps. With each subsequent generation of recombinant factor VIII products, the use of human proteins has been reduced.[19]

Significant advancements have taken place in the development of long-acting factor VIII and IX products some of which are Food and Drug Administration approved and commercially available. Methods for prolonging the half-life of these products include pegylation and Fc fusion.[20] Pegylation is thought to increase half-life by protecting the factor from receptor-mediated uptake and enzymatic catabolism. It reduces renal clearance and levels of neutralizing antibodies due to steric hindrance.[19] Protein fusion has also been a successful approach to prolonging the half-life of factor products. This method fuses factor VIII or IX to another human protein with a long circulatory half-life such as albumin or immunoglobulin G (IgG). These fused proteins then bind to the neonatal Fc receptor, or FcRn, present in the acidified endosomes of the endothelial cells. This binding protects the factor fusion product from targeted lysosomal degradation and facilitates recycling of the neonatal Fc receptor ligands at the endothelial surface resulting in a prolonged systemic half-life of the factor.[21,22]

Table 123-2 summarizes many of the factor VIII products available in the United States. Most patients are treated with high-purity products, which generally have the lowest risk of transmitting infectious disease and are therefore recommended as first-line agents.[1] Recombinant products, when available, are generally used rather than plasma-derived products.

TABLE 123-2

Factor Concentrates

Plasma Derived	Recombinant	Extended Half-Life
• **Factor VIII** ◦ Hemofil M ◦ Koate DVI ◦ Monoclate P • **Factor VIII + vWF** ◦ Alphanate ◦ Humate P ◦ Wilate • **Factor IX** ◦ AlphaNine ◦ Mononine • **PCC** ◦ Bebulin ◦ Kcentra ◦ Profilnine • **aPCC** ◦ FEIBA	• **Factor VIII** ◦ Advate ◦ Afstyla ◦ Helixate ◦ Kogenate ◦ Kovaltry ◦ Obizur (PS) ◦ Recombinate ◦ Nuwiq ◦ NovoEight (BDD) ◦ Xyntha (BDD) • **Factor IX** ◦ BeneFIX ◦ Ixinity ◦ Rixubis • **Factor VII** ◦ NovoSeven • **vWF** ◦ Vonvendi	• **Factor VIII** ◦ Adynovate (PEG) ◦ Jivi (PEG) ◦ Eloctate (Fc-IgG) • **Factor IX** ◦ Alprolix (Fc-IgG) ◦ Idelvion (FP) ◦ Rebinyn (PEG)

BDD, B-domain deleted; Fc-IgG, fusion protein IgG; FP, fusion protein–albumin; PCC, prothrombin complex concentrate; PEG, pegylated; PS, porcine sequenced; vWF, von Willebrand Factor.

Recombinant Factor VIII

③ Recombinant factor VIII is produced with recombinant DNA technology and is derived from cultured Chinese hamster ovary cells or baby hamster kidney cells transfected with the human factor VIII gene.[5] Since these products are not derived from blood donations, the risk of transmitting infections through administration of recombinant factor VIII is low and recombinant products are generally favored over plasma-derived products. A small risk of viral infection of the cell lines used to produce the clotting factor still remains. Furthermore, human or animal proteins are used in the production process of some recombinant products.[19] Therefore, these products have a theoretical risk of transmitting infection, although hepatitis and HIV infection have never been reported with their use.[5] First-generation recombinant factor VIII products contain human albumin as a stabilizing protein.[5] Second-generation recombinant factor VIII products add sugar instead of human albumin as a stabilizer, but human albumin is used in the culture process. Several products are manufactured specifically with the B domain of the factor VIII gene deleted, yielding a smaller protein product.[5,23] This B domain does not appear to be necessary for coagulation function and may serve as a binding site for neutralizing antibodies. Third-generation recombinant factor VIII products do not contain human protein either in the culture or in the stabilization processes.[19]

Plasma-Derived Factor VIII Products

The recombinant factor VIII products are comparable in effectiveness to plasma-derived products.[5] Several different plasma-derived factor VIII products are available (Table 123-2). These products are derived from the pooled plasma of thousands of donors and therefore have the potential to transmit infection. Donor screening, testing of plasma pools for evidence of infection, viral reduction through purification steps, and viral inactivation procedures (eg, dry heat, pasteurization, and solvent detergent treatment) have resulted in a safer product. No cases of HIV transmission from factor concentrates have been reported since 1986.[5] However, isolated cases of hepatitis C infection with the use of plasma-derived products have been reported.[5] Additionally, outbreaks of hepatitis A viral infections associated with plasma-derived products have been reported, likely because solvent detergent treatment does not inactivate this nonenveloped virus. Finally, possible infection with unidentified viruses not inactivated by the currently used methods remains a concern. In addition, Prion disease may be present in plasma-derived factor products.[24]

Factor VIII concentrates can be classified according to their level of purity, which refers to the specific activity of factor VIII in the product. Cryoprecipitate is a low-purity product that also contains vWF, fibrinogen, and factor XIII. The American Association of Blood Banks standards call for a minimum of 80 international units of factor VIII per cryoprecipitate pack.[5] This product is no longer considered a primary treatment of factor VIII deficiency in countries where factor VIII concentrates are available because cryoprecipitate does not undergo a viral inactivation process. Intermediate-purity products have a specific factor VIII activity of 5 units/mg of protein and high-purity products have up to 2,000 units/mg of protein.[5] Ultrahigh-purity plasma-derived products are prepared with monoclonal antibody purification steps and have a specific activity of 3,000 units/mg of protein prior to addition of albumin as a stabilizer.

Factor VIII: Dosing

Appropriate dosing of factor VIII concentrate depends on the half-life of the infused factor, the patient’s body weight, and the location and severity of the bleed. The presence or absence of an inhibitory antibody to factor VIII and the titer of this antibody also influence treatment. Recovery studies, which measure the immediate postinfusion factor level, and survival studies, which assess the half-life of the factor, can establish patient-specific pharmacokinetics. The location and magnitude of the bleeding episode determine the percent correction to target as well as the duration of treatment. Serious or life-threatening bleeding requires peak factor levels of greater than 0.75 to 1 units/mL (75%-100%); less severe bleeding may be treated with a goal of 0.3 to 0.5 units/mL (30%-50%) peak plasma levels. Table 123-3 provides general guidelines for the management of bleeding in different locations.

TABLE 123-3

Guidelines for Factor Replacement Therapy for Hemorrhage in Hemophilia A and B

Site of Hemorrhage	Desired Hemostatic Factor Level (% of Normal)	Comments
Joint	50%-70%, 2-3 days	Rest/immobilization/physical therapy rehabilitation following bleed; several doses may be necessary to prevent or treat target joint
Muscle	30%-50% for most sites	Risk of significant blood loss with a thigh or iliopsoas bleed; bed rest for iliopsoas or thigh bleeding
	70%-100% for thigh, iliopsoas, or nerve compression	
Oral mucosa	30%-50%	May try antifibrinolytic or topical thrombin prior to factor replacement for minor bleeding; higher factor levels are needed for tongue swelling or risk of airway compromise; antifibrinolytic therapy should be used following factor replacement
Gastrointestinal	Initially 100%, then 40%-60%	Endoscopy is highly recommended; antifibrinolytic therapy may be useful. Continue until healing occurs
Hematuria	30%-50% if no trauma	If no pain or trauma, consider bed rest and fluids for 24 hours; factor should be given if hematuria persists; evaluate if hematuria persists; if trauma to abdomen or back, perform imaging and give aggressive factor replacement
	70%-100% if traumatic	
Central nervous system	Initially 100%, then 50%-100% for 10-21 days	Lumbar puncture requires prophylactic factor coverage
Trauma or surgery	Initially 100%, then 50%-100% until wound healing complete	The perioperative and postoperative management plan must be in place preoperatively; evaluation for inhibitors is crucial prior to elective surgery

Factor VIII is a large molecule that remains in the intravascular space. Therefore, the plasma volume (about 50 mL/kg) can be used to estimate the volume of distribution. In general, each unit of factor VIII concentrate infused per kilogram of actual body weight results in a 2% rise in plasma factor VIII levels.[1] The following equation can be used to calculate an initial dose of factor VIII:

$$\text{Factor VIII (units)} = (\text{Desired level} - \text{Baseline level}) \times 0.5 \times (\text{Weight [in kilograms]})$$

Factor VIII (units)=(Desired level - Baseline level)×0.5×(Weight [in kilograms])

The baseline level usually is omitted from the equation when it is negligible compared to the desired level. The half-life of factor VIII ranges from 8 to 15 hours. It is generally necessary to administer 50% of the initial dose about every 12 hours to sustain the desired level of factor VIII. A single treatment may be adequate for minor bleeding, such as oral bleeding or slight muscle hemorrhages. However, because of the potential for long-term joint damage with hemarthroses, 2 or 3 days of treatment is often recommended for these bleeds. Serious bleeding episodes may require maintenance of 70% to 100% (0.7-1.0 units/mL) factor activity for 1 week or longer. As previously mentioned, factor VIII dosing depends on several variables, and each case must be considered individually. Individualized pharmacokinetics may help guide treatment, particularly for serious bleeding episodes.

Alternatively, factor VIII can be administered as a continuous infusion when prolonged treatment is required (eg, in the perioperative period or for serious bleeding episodes). Infusion rates ranging from 2 to 4 units/kg/hr usually are given in fixed-dose continuous infusion protocols, with the aim of maintaining a steady-state level of 60% to 100% (0.6-1.0 units/mL).[25] Administration of factor concentrate via continuous infusion may reduce factor requirements by 20% to 50% because unnecessarily high peaks of factor VIII that occur with bolus injections are avoided. A gradual decrease in factor VIII clearance during the first 5 to 6 days of treatment contributes to the lower factor concentrate requirements. Daily monitoring of factor level can help determine the appropriate rate of infusion.

Administration of factor VIII concentrate via continuous infusion is safe and effective, and it may be more convenient than bolus therapy for hospitalized patients.[26] Concerns about the stability of the formulations appear to be unwarranted, as most high-purity factor VIII concentrates remain stable for at least 7 days after reconstitution.[26] However, exposure of factor VIII to light for 10 hours after reconstitution can decrease activity by 30% (0.3 units/mL).[26] Therefore, it would be prudent to shield the container with foil wrap or an appropriate bag.

Other Pharmacological Therapy

Treatment with desmopressin acetate often is adequate for minor bleeding episodes in patients with mild hemophilia A. A synthetic analog of the antidiuretic hormone vasopressin, desmopressin causes the release of vWF and factor VIII from endogenous endothelial storage sites. It is most effective in patients with higher baseline factor VIII levels (0.1-0.15 units/mL [10%-15%]).[25] The recommended dose of desmopressin is 0.3 mcg/kg diluted in 50 mL of normal saline and infused IV over 15 to 30 minutes.[25] Patients with mild or moderate hemophilia A should undergo a desmopressin trial to determine their response to this medication. At least a twofold rise in factor VIII to a minimal level of 0.3 units/mL (30%) within 60 minutes is considered an adequate response.[1,25] Infusion of desmopressin can be repeated daily for up to 2 to 3 days. Tachyphylaxis, an attenuated response with repeated dosing, may develop after that time due to the depletion of factor stores. The factor increase after the second dose of desmopressin is about 30% lower than after the initial dose.[27] Factor concentrate therapy may be necessary if the patient requires additional treatment. Factor levels should be monitored to ensure that an adequate response has been achieved. Treatment with desmopressin will not result in hemostasis in patients who have severe hemophilia and those who are only marginally responsive. Desmopressin should not be used as primary therapy for life-threatening bleeding episodes such as intracranial hemorrhage or for major surgical procedures.[1]

Desmopressin can be administered intranasally via a concentrated nasal spray.[25] It elicits a slower and less marked response, with a peak effect in 60 to 90 minutes after administration, which is somewhat longer than with IV administration.[25,27] The dosage is one spray (150 mcg) in one nostril for patients who weigh less than 50 kg and two sprays (one in each nostril, 300 mcg total) for those who weigh more than 50 kg.[25] The nasal spray may serve as an alternative to the IV formulation, especially in patients with mild bleeding episodes. Few adverse drug reactions are associated with desmopressin. The most commonly observed adverse drug reaction is facial flushing.[27] Less frequently reported adverse drug reactions include mild headaches, increased heart rate, and decreased blood pressure. Desmopressin can cause water retention because of its antidiuretic effects, which may lead to severe hyponatremia. This may be a particular problem in children younger than 2 years and, therefore, should be used with caution in this age group.[25] Fluid restriction for 24 hours after the desmopressin dose and monitoring of urine output are recommended with desmopressin administration.[25]

Antifibrinolytic therapy inhibits clot lysis and therefore is a useful adjunctive therapy for the treatment of hemophilia, primarily with mucocutaneous bleeding. Antifibrinolytic agents are particularly beneficial for the treatment of oral bleeding because of a high concentration of fibrinolytic enzymes in saliva. Antifibrinolytic therapy can also be helpful as adjuvant therapy in GI bleeding, epistaxis, and menorrhagia. Antifibrinolytic therapy should be used with caution in patients with urinary bleeding, due to the risk of obstruction and subsequent renal toxicity. The two available antifibrinolytics include aminocaproic acid and tranexamic acid. Aminocaproic acid is given at a dosage of 100 mg/kg (maximum 6 g) every 6 hours and can be administered orally or IV.[5] The dosage of tranexamic acid is 25 mg/kg (maximum 1.5 g) orally every 6 to 8 hours.[5]

Hemophilia B

Therapeutic options for hemophilia B have improved greatly over the past several years, first with the development of monoclonal antibody-purified plasma-derived products and then with the licensure of recombinant factor IX. Products available in the United States for treatment of hemophilia B are listed in Table 123-2.

Recombinant Factor IX

Recombinant factor IX was not available until 1998, which is 6 years after the first recombinant factor VIII product.[19] The first commercially available recombinant factor IX is produced in Chinese hamster ovary cells transfected with the factor IX gene. Since blood and plasma products are not used to produce recombinant factor IX or to stabilize the final product, recombinant factor IX has an excellent viral safety profile.[5] Clinical trials have proved the safety and efficacy of the product in the treatment of acute bleeding episodes and in the management of bleeding associated with surgical procedures.[5] Although the half-life of recombinant factor IX is similar to that of the plasma-derived products, recovery is about 30% lower.[25] As a result, doses of recombinant factor IX concentrate must be higher than those of plasma-derived products to achieve equivalent plasma levels. Because individual pharmacokinetics may vary, recovery and survival studies should be performed to determine optimal treatment.[5] Recombinant factor IX is considered the treatment of choice for hemophilia B.[1]

Plasma-Derived Factor IX Products

High-purity factor IX plasma concentrates have been available in the United States since the early 1990s.[5,19] These products are derived from plasma through biochemical purification and monoclonal immunoaffinity techniques. Other viral inactivation measures, such as solvent detergent or chemical treatment, are also used. High-purity factor IX concentrates have excellent efficacy in the treatment of bleeding episodes and in the control of bleeding associated with surgical procedures.[25] Their viral safety profile has been reported to be excellent and the risk of thromboembolic complications is low.

Before the high-purity products were approved for use, hemophilia B patients were treated with factor IX concentrates that also contained other vitamin K–dependent proteins (factors II, VII, and X), known as prothrombin complex concentrates (PCCs). These products contain small amounts of activated factors generated during processing, and their use has been associated with thrombotic complications, including deep-vein thrombosis, pulmonary embolism, myocardial infarction, and disseminated intravascular coagulation.[5,25] The risk of these complications is highest in patients receiving high or repeated doses of PCCs, in those with hepatic disease (the liver produces antithrombotic factors and removes the activated factors from circulation), in neonates, and in patients who have experienced crush injuries or who are undergoing major surgery.[5] Concomitant use of PCCs and antifibrinolytics should be avoided because of the risk for thrombosis. Because of the lower purity of PCCs and their thrombogenic potential, these products are not first-line treatment for hemophilia B.

Factor IX: Dosing

Factor IX is a relatively small protein. Unlike factor VIII, it is not limited to the intravascular space; it also passes into the extravascular compartment.[5] Therefore, it has a volume of distribution that is about twice that of factor VIII. For plasma-derived factor IX concentrates, each unit of factor IX infused per kilogram of actual body weight results in about a 1% (0.01 units/mL) rise in the plasma level of factor IX (range, 0.67%-1.28% [0.0067-0.0128 units/mL]).[5] The following equation can be used to calculate the initial dose:

$$\text{Plasma} - \text{derived factor IX (units)} = (\text{Desired level} - \text{Baseline level}) \times (\text{Weight [in kilograms]})$$

Plasma-derived factor IX (units)= (Desired level - Baseline level) × (Weight [in kilograms])

As with the factor VIII dose calculation, the baseline level term can be omitted from the formula if it is negligible compared to the desired level. Because recovery of recombinant factor IX is lower than that of the plasma-derived products, the following adjustment is made:

Pediatric dosing:

$$\text{Recombinant factor IX (units)} = (\text{Desired level} - \text{Baseline level}) \times 1.4 \times (\text{Weight [in kilograms]})$$

Recombinant factor IX (units) = (Desired level - Baseline level) × 1.4 × (Weight [in kilograms])

Adult dosing:

$$\text{Recombinant factor IX (units)} = (\text{Desired level} - \text{Baseline level}) \times 1.2 \times (\text{Weight [in kilograms]})$$

Recombinant factor IX (units) = (Desired level - Baseline level) × 1.2 × (Weight [in kilograms])

A recovery study to determine optimal dosing is recommended for patients who receive recombinant factor IX because of the wide interpatient variability in pharmacokinetics. Because the half-life of factor IX is about 24 hours, dosing can be less frequent than with factor VIII. Table 123-3 provides general guidelines for dosing factor IX based on the site and severity of the bleeding episode.[25]

Treatment of Inhibitors

④ Neutralizing antibodies to factors VIII and IX, known as *inhibitors*, develop in a subset of patients with hemophilia. The development of an inhibitor is the most serious complication of factor replacement therapy and is associated with considerable morbidity and a decreased quality of life. The incidence of new factor VIII inhibitors in patients with severe factor VIII deficiency is about 30%.[28] Inhibitors are less common in patients with mild or moderate hemophilia occurring in about 5% to 10% of patients.[1] The risk of developing inhibitors in patients with hemophilia B is much lower, occurring in only 3% of patients.[5]

An inhibitor is a polyclonal high-affinity IgG directed against the factor VIII or IX protein. Inhibitors interfere with infused factor concentrate, rendering them ineffective. The presence of an inhibitor is suspected when a decreased clinical response to factor replacement is observed or it may be discovered incidentally on routine laboratory screening. Inhibitors are measured with the Bethesda assay, and titers are reported in Bethesda units (BUs). One BU is the amount of inhibitor needed to inactivate half of the factor VIII or factor IX in a mixture of inhibitor-containing plasma and pooled normal plasma.[5] Patients with inhibitors to factor VIII or factor IX are divided into two groups: low responders, who have low levels of inhibitors (5 BU/mL), and high responders who have higher inhibitor levels (>5 BU/mL) and develop an increase in antibody titer after exposure (anamnestic response).[5,29]

Most inhibitors develop in childhood, after relatively few exposure days (median 9-12 days).[30] Patients with severe hemophilia are much more likely to develop inhibitors than those with milder forms of the disease.[29] It is possible that the low levels of factor produced in patients with mild or moderate hemophilia induce immune tolerance in these individuals. In contrast, factor levels are undetectable in patients with severe hemophilia, so infused factor VIII is regarded as a foreign protein, which may provoke an antibody response. The rate of inhibitor formation varies even among patients with identical mutations, which suggests that host factors modify the risk. The development of an inhibitor is the result of a complex interaction between a patient's immune system and genetic and environmental risk factors.

The type of factor product administered to patients may influence the risk of developing inhibitors. An international, multicenter, randomized, open-label clinical trial named Survey of Inhibitors in Plasma-Product Exposed Toddlers, or SIPPET, was designed to evaluate the incidence of inhibitor development in previously untreated or minimally treated patients with hemophilia A exposed to plasma-derived factor products compared to recombinant products.[31] The results of this pivotal trial showed that patients receiving recombinant factor VIII products had a significantly higher incidence of developing inhibitors compared to those receiving plasma-derived products.

Therapy for patients with inhibitors involves the treatment of acute bleeding episodes and treatment directed at eradicating the inhibitor. The inhibitor titer, the site and magnitude of bleeding, and the patient's past response to bypassing therapy determine the approach to the treatment of acute bleeding. For patients with a low inhibitor titer, the administration of high doses of the specific factor often can control bleeding episodes. Two to three times the usual replacement dose and more frequent dosing intervals are often necessary to overcome the antibody. Factor-level monitoring and clinical assessments help to evaluate the adequacy of treatment. Additional supportive measures, such as immobilization and administration of antifibrinolytic agents, should be used, where appropriate.[1]

Treatment of acute bleeds in patients with high-titer inhibitors can be complicated and require the use of alternative agents. In the presence of a high-titer inhibitor, it is impossible to administer enough factor VIII or factor IX to neutralize the antibody and achieve a hemostatic plasma level. Therefore, the treatment of bleeding episodes consists of agents that bypass the factor to which the antibody is directed. These bypassing agents include PCCs, aPCCs, and recombinant factor VIIa. PCCs contain the vitamin K–dependent factors II, VII, IX, and X. Small quantities of activated factors are present in these products. Activated PCCs contain greater quantities of the activated factors, primarily factor X and prothrombin. The only available aPCC product in the United States is FEIBA® (Factor Eight Inhibitor Bypassing Agent). The recommended dosage is 50 to 100 units/kg administered every 8 to 12 hours, depending on the severity of the bleeding episode and the maximum dose should not exceed 200 units/kg/day.[15] Activated PCCs appear to be more effective than PCCs and are preferred in patients with inhibitors. As previously mentioned, serious thrombotic complications, including pulmonary emboli, deep-vein thrombosis, and myocardial infarction, have been associated with the use of PCCs and aPCCs.[15] Other minor adverse drug reactions include dizziness, nausea, hives, flushing, and headaches. Patients with factor IX inhibitors occasionally develop severe allergic reactions in response to infusion of factor IX-containing products, so these patients should be monitored closely.[29]

⑤ Recombinant factor VIIa is effective for the treatment of acute bleeds in patients with hemophilia A or B who have developed inhibitors. Recombinant factor VIIa is a bypassing agent that is thought to be hemostatically active only at the site of tissue injury where the tissue factor is present. Recombinant factor VIIa is not a plasma-derived product, so both viral transmission and anamnestic responses to factor VIII or factor IX are unlikely. The initial recommended dose for bleeding episodes is 90 mcg/kg.[15] However, depending on a patient's response, higher doses up to 300 mcg/kg can be used. A drawback is the product's short half-life, which necessitates initial dosing every 2 hours. Continuous infusion of recombinant factor VIIa, which may be more convenient and cost-effective, has been reported.[32] Patients treated with bypassing agents must be monitored clinically because no laboratory test directly measures the effectiveness of treatment.

Both recombinant factor VIIa and aPCCs are effective in the treatment of bleeding for patients with inhibitors. In determining which bypassing product to use in an individual patient, the clinician must consider multiple factors. In a patient with a newly diagnosed inhibitor, it is prudent to use recombinant factor VIIa because aPCCs contain a small amount of factor VIII or IX and increase the inhibitor titer. It is also important to consider an individual's response to specific bypassing agents because of the significant variability in response between individuals. In some patients, bleeding can be unresponsive to monotherapy and may require alternating products.[33] Due to the risk of developing thrombosis or disseminated intravascular coagulation from alternating bypassing agents, this therapy should be used with caution and only in an inpatient setting.[15]

In the past, plasma-derived porcine factor VIII was an alternative therapeutic option for patients who have hemophilia A and inhibitors. It was removed from the market secondary to contamination with porcine parvovirus. The rationale for its use is that porcine factor VIII is enough like human factor VIII to participate in the coagulation cascade, yet most factor VIII inhibitors have absent or only weak neutralizing activity against nonhuman factor VIII making this an effective agent to treat an acute bleed. Unfortunately, cross-reactivity with porcine factor VIII does occur, and a high titer of antibody against porcine factor VIII can develop and hypersensitivity to porcine proteins can occur. A recombinant porcine factor VIII has been approved, but only for the treatment of acute bleeds in patients with acquired hemophilia A.[15,34]

The hemostatic therapies for patients with an inhibitor have limited effectiveness leading to significant morbidity and a decreased quality of life. The ideal therapy for patients with an inhibitor is total eradication so that optimal hemostatic treatment with either factor VIII or IX is possible. At this time, the only proven method for inhibitor eradication is immune tolerance induction (ITI), which involves the regular infusion of factor VIII to induce antigen-specific tolerance. This approach is not recommended for patients with hemophilia B who have developed inhibitors due to the risk of hypersensitivity reactions and anaphylaxis associated with factor IX administration in this group.

Multiple immune tolerance registries were established to help determine patient- and treatment-related factors associated with immune tolerance outcome.[35] Across these registries, a patient's peak historical factor VIII inhibitor titer (<200 BU) and the inhibitor titer at the time of ITI induction (<10 BU) were associated with successful immune tolerance. The overall ITI success rate from these registries ranges from 51% to 79%; the variability is likely related to a lack of standardization in study methodologies, treatment protocols, and eradication definitions.[35,36]

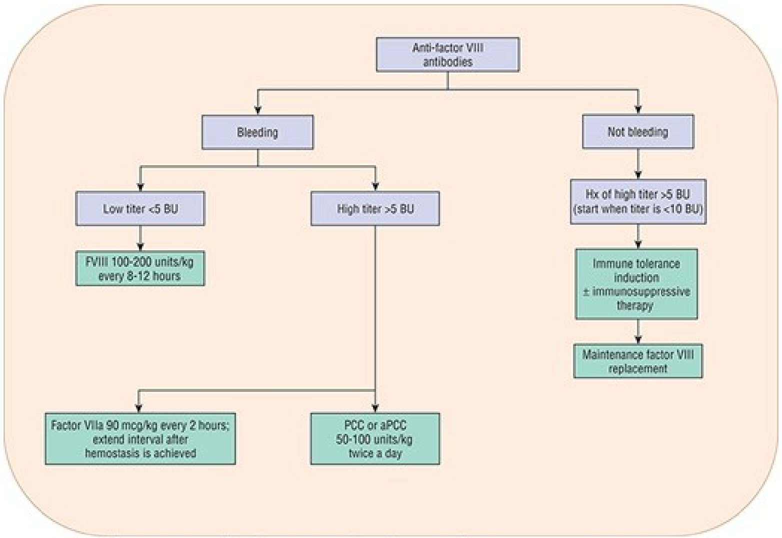
The relationship between factor VIII dose and ITI success rate is not clear. A variety of different dosing regimens, ranging from 25 units/kg every other day to more than 200 units/kg every day, have been used. The International Immune Tolerance Registry demonstrated improved ITI success with high doses (200 IU/kg), while the North American and Spanish Immune Tolerance Registries showed improved success with lower dosing strategies.[36] The International Immune Tolerance Study is a multicenter randomized clinical trial that compared high-dose (200 units/kg/day) to low-dose (50 units/kg three times/week) regimens in patients with severe hemophilia A and high titer inhibitors (>5 BU).[35] This study was stopped early due to an increased risk of bleeding events in the low-dose arm. At the stopping point, the proportion of ITI success was not significantly different between the two arms, but the time to achieve ITI success was shorter in the high-dose arm. Because the study was stopped early, it lacked statistical power to demonstrate therapeutic equivalence below the 30% boundary of equivalence. A high-dose strategy achieves tolerance at a faster rate, which explains the lower bleeding rate.

Some studies report better success rates for ITI in patients receiving plasma-derived factor products containing vWF, which may be related to the role of vWF in factor VIII function, stabilization, and immunogenicity.[37] vWF binding to the C2 domain of factor VIII, a common site for inhibitor formation, may result in epitope masking and decreased inhibitor activity. The use of vWF-containing products may also extend the plasma half-life of factor VIII during ITI; thus, increasing antigen presentation and possibly contributing to its overall success.[37]

Although not commonly used in ITI protocols, immune modulation can improve tolerance success. Agents such as cyclophosphamide and intravenous immune globulin have been used to reduce inhibitor titers and make ITI more successful.[1] Another immune modulating agent, rituximab, an anti-CD20 monoclonal antibody that inhibits B-cells and interferes with IgG production, has been used with some success. In a phase II trial of rituximab in patients with high titer inhibitors, only 3 out of 16 subjects (18.8%) had a major response (decline in the inhibitor to <5 BU without an increase in the inhibitor titer after rechallenge to factor VIII).[38] When used as a single agent in previously treated patients with inhibitors, rituximab had a modest effect, but further studies are needed to determine the activity of rituximab combined with ITI. Figure 123-1 summarizes the therapeutic options in the management of acute bleeding in patients with hemophilia A and inhibitors.

FIGURE 123-1

Treatment algorithm for the management of patients with hemophilia A and factor VIII antibodies. (aPCC, activated prothrombin complex concentrate; BU, Bethesda unit; PCC, prothrombin complex concentrate)



Anti-factor VIII antibodies
Bleeding
Not bleeding
Low titer <5 BU
High titer >5 BU
Hx of high titer >5 BU (start when titer is <10 BU)
FVIII 100-200 units/kg every 8-12 hours
Immune tolerance induction ± immunosuppressive therapy
Maintenance factor VIII replacement
Factor VIIa 90 mcg/kg every 2 hours; extend interval after hemostasis is achieved
PCC or aPCC 50-100 units/kg twice a day

Gene Therapy

Hemophilia is an excellent candidate for gene therapy because tight control of gene expression is not required. Even low levels of factor expression can reduce bleeding episodes in patients with severe hemophilia, which is similar to the rationale for prophylactic factor replacement. The goal of gene therapy is to achieve a sustainable factor activity level of over 5% (0.05 units/mL), which is sufficient to convert patients with severe disease to a much milder phenotype.[39,40] If a treatment strategy could produce consistent factor activity levels of around 50% (0.5 units/mL), it would be considered curative.[40] Potential benefits to gene therapy include patient convenience, viral safety, and decreased cost. Possible drawbacks to gene therapy include a risk of inhibitor formation, tumorigenesis related to possible integration of the viral vector, possible germline transmission of the viral vector, and concerns about long-term gene expression.

Gene therapy for the treatment of hemophilia remains in the early clinical stages. Advances are most apparent in hemophilia B, which has been attributed to the smaller size (about 1.4 kb) of its complementary DNA (cDNA).[40] A landmark clinical trial reported the results of a single peripheral venous infusion of an adenovirus associated factor IX transgene vector under the control of a liver-restricted promoter in six patients with severe hemophilia B.[41] All of the study subjects showed long-term (over 2 years) expression of the factor IX transgene with therapeutic levels of factor IX (plateau factor IX levels from 1% to 6% [0.01-0.06 units/mL]).[41]

Gene therapy for factor VIII deficiency has been challenging due to the considerably larger size of its cDNA (about 9 kb).[40] The development of B-domain deleted factor VIII has been beneficial in allowing a smaller amount of cDNA to be able to be packaged into a single vector. A multi-year follow-up of the original clinical trial of Adeno-associated virus (AAV) serotype 5 human factor VIII (hFVIII) SQ (valoctocogene roxaparvovec) was published reporting safety and efficacy data for up to 3 years in the original 15 patients enrolled in this dose escalating study. Patients were enrolled into four escalating dose cohorts. All patients experienced at least one adverse drug reaction; however, all of these were considered mild and transient. No participants dropped out of the study. After 3 years of follow-up one patient had factor VIII levels in the non-hemophilic range, 11 patients had levels in the mild hemophilic range, one patient in the moderate hemophilic range, and two patients (dose level one and dose level two) still have factor VIII levels in the severe hemophilic range. So far this 3-year follow-up does show that the decline in factor levels over time does decrease. No cellular immune response was consistently detected against factor VIII or the AAV serotype 5 capsid in any patient. No factor VIII inhibitors or other antibodies directed to components of factor VIII have been detected in any of the patients.[40]

Other areas of gene therapy are being explored for the treatment of hemophilia. Platelets derived from hematopoietic stem cells may be able to deliver factor VIII or IX directly into the circulation. Lentiviral vectors are being explored for gene therapy due to their much larger packaging capacities compared to the adeno-associated viral vector AAV. The area of gene editing is also being explored for patients with hemophilia using zinc finger nucleases or clustered regularly interspaced short palindromic repeats (CRISPR) approaches.[41]

Pain Management

Pain, both acute and chronic, can be a common occurrence in patients with hemophilia. The most likely cause of acute pain is bleeding, and treatment should include factor replacement to stop the bleeding, and PRICE (Protect, Rest, Ice, Compression, and Elevation).[1,42] Acetaminophen can be used for mild pain, although narcotic analgesia may be required for more severe pain. NSAIDs impair platelet function and may complicate bleeding. For this reason, nonspecific NSAIDs are not routinely recommended during acute bleeding episodes. Cyclooxygenase-2 inhibitors have less antiplatelet activity and are an option for acute and chronic pain management.[1,42]

Chronic pain in patients with hemophilia is typically secondary to hemophilic arthropathy. Hemophilic arthropathy is the direct result of recurrent hemarthrosis. Persistent blood in the joint leads to inflammation, synovial hypertrophy and inflammation, cartilage destruction, and finally bony erosion. Cyclooxygenase-2 inhibitors can also be help manage chronic pain. Surgical interventions may help to alleviate chronic pain. Synovectomy (removal of the hypertrophied synovium) can reduce chronic pain from recurrent bleeding. Patients with more advanced joint disease could benefit from joint replacement.

Surgery

In patients with severe hemophilia, the dose of replacement factor required in the perioperative period will depend on the surgery, the inhibitor status, and the patient's previous response to factor products. Ideally, the patient's factor activity level should be maintained in the range of 50% to 100% (0.5-1.0 units/mL) depending on clinical status and type of procedure. Intermittent dosing or continuous infusion factor replacement may accomplish this goal.[1,32,43] Before surgery, factor concentrate is usually infused to obtain a plasma level of 1 unit/mL (100%). Replacement therapy is continued to maintain plasma levels greater than 0.5 units/mL (50%) for 5 to 7 days or longer, depending on the type of surgery and the patient's clinical response. Preoperative evaluation for elective procedures should include measurement of an inhibitor titer no longer than 2 weeks prior to procedure and assessment of the recovery and half-life of infused factor in the patient.[1] For those patients with inhibitors undergoing surgical procedures, there is evidence to support the use of both activated factor VII and aPCCs.[1,32]

Evaluation of Therapeutic Outcomes

The main goal in the treatment of hemophilia is to control and prevent bleeding episodes and their long-term sequelae such as chronic arthropathies. Pharmacologic and nonpharmacologic interventions should be aimed at achieving this goal. Treatment response can be monitored through clinical parameters such as cessation of bleeding and resolution of symptoms. Monitoring plasma factor levels also may be helpful, particularly for severe bleeding episodes. Home therapy for administration of factor concentrates is common among patients with hemophilia because this approach can lead to earlier treatment and more independence for the patient. Diaries in which the patient documents symptoms, the dose of factor replacement, adjuvant therapies used, and treatment response can help the caregiver to evaluate the success of home therapy. Monitoring the number and type of bleeding episodes and trough plasma factor levels can evaluate the adequacy of prophylactic regimens. Pharmacokinetically driven dosing for prophylactic factor could optimize therapy, reduce bleeding and decrease overall factor consumption for the patient.[44] Physical examination with evaluation of joint range of motion and radiographic imaging of target joints can evaluate the long-term success of preventing and treating arthropathies.[44]

Clinicians should check for the development of inhibitors, especially in patients with severe disease and exposure to factor concentrates, at least yearly and with any suspicion of poor treatment response. The development of inhibitors challenges the management and control of bleeding episodes. A full understanding of the clinical situation and the titer of the inhibitor are mandatory to address all treatment options for each patient. Because no laboratory test measures the effectiveness of bypassing therapy in patients with inhibitors, close clinical monitoring for worsening or resolution of symptoms is essential for optimizing the outcome.[1]

VON WILLEBRAND DISEASE

von Willebrand disease (vWD) is the most common congenital bleeding disorder in the United States and in the world, with a prevalence of 0.1% to 1%.[45] vWD refers to a family of disorders caused by a quantitative and/or qualitative defect of vWF, a glycoprotein that plays a role in both platelet aggregation and coagulation (Table 123-4). vWF mediates platelet adhesion to injured blood vessel sites and promotes platelet aggregation. It binds factor VIII and protects it from degradation by plasma proteases, thus prolonging its half-life. Unlike hemophilia, vWD has an autosomal inheritance pattern, resulting in an equal frequency of disease in males and females. Diagnosis of vWD may be more prevalent in females due to female-specific hemostatic challenges, such as child birth and menstruation.

TABLE 123-4

von Willebrand Disease—Blood Tests

von Willebrand factor (vWF)	Large multimeric glycoprotein that is necessary for normal platelet adhesion, normal bleeding time, and stabilization of factor VIII
von Willebrand factor antigen (vWF:Ag)	Antigenic determinant(s) on vWF measured by immunoassays; usually low in types 1 and 2; virtually absent in type 3
Ristocetin cofactor activity (RCo)	Functional assay of vWF activity based on platelet aggregation with ristocetin. Reduced by the same degree as vWF:Ag in types 1 and 3, but to a greater extent in type 2 disease (except 2B)
Glycoprotein Ib with gain-of-function mutation (vWF:GPIbM)	Functional assay of vWF binding to a fragment of recombinant glycoprotein Ib; usually low in types 1 and 2; virtually absent in type 3
Glycoprotein Ib with ristocetin-dependent binding (vWF:GPIbR)	Functional assay utilizing ristocetin, recombinant glycoprotein Ib fragments, and microparticles, rather than whole platelets; usually low in types 1 and 2; virtually absent in type 3

Transcription and translation produce a large primary product that subsequently undergoes complex modifications, resulting in vWF multimers of various sizes. vWF is synthesized in endothelial cells, where it is either stored in Weibel–Palade bodies or secreted constitutively. It is also synthesized in megakaryocytes and stored in α-granules, from which it is released following platelet activation.[46,47]

vWF is important for both primary and secondary hemostasis. In response to vascular injury, it promotes platelet adhesion by interacting with the glycoprotein Ib receptor on platelets.[47] It can facilitate platelet aggregation by binding to the platelet glycoprotein IIb/IIIa receptor, although fibrinogen is the main ligand for this receptor.[48] The highest-molecular-weight vWF multimers are the most important in platelet adhesion because their large surface area contains numerous binding sites for various ligands and receptors. vWF is also the carrier molecule for circulating factor VIII, protecting it from premature degradation and removal.[46,47] A deficiency of vWF reduces the half-life of factor VIII and decreases plasma factor VIII levels. Therefore, vWF plays a dual role in hemostasis, affecting both platelet function and coagulation.

Classification of von Willebrand Disease

vWD consists of a heterogeneous group of disorders that can be classified into three major subtypes. The National Institutes of Health has developed a classification scheme that characterizes vWD according to both the quantity of the von Willebrand clotting factors and their functionality (Fig. 123-2). Types 1 and 3 are associated with quantitative defects in vWF; type 2 mutations refer to functional abnormalities in vWF (qualitative defects).[45,47,48] It is important to determine disease subtype because it influences treatment.

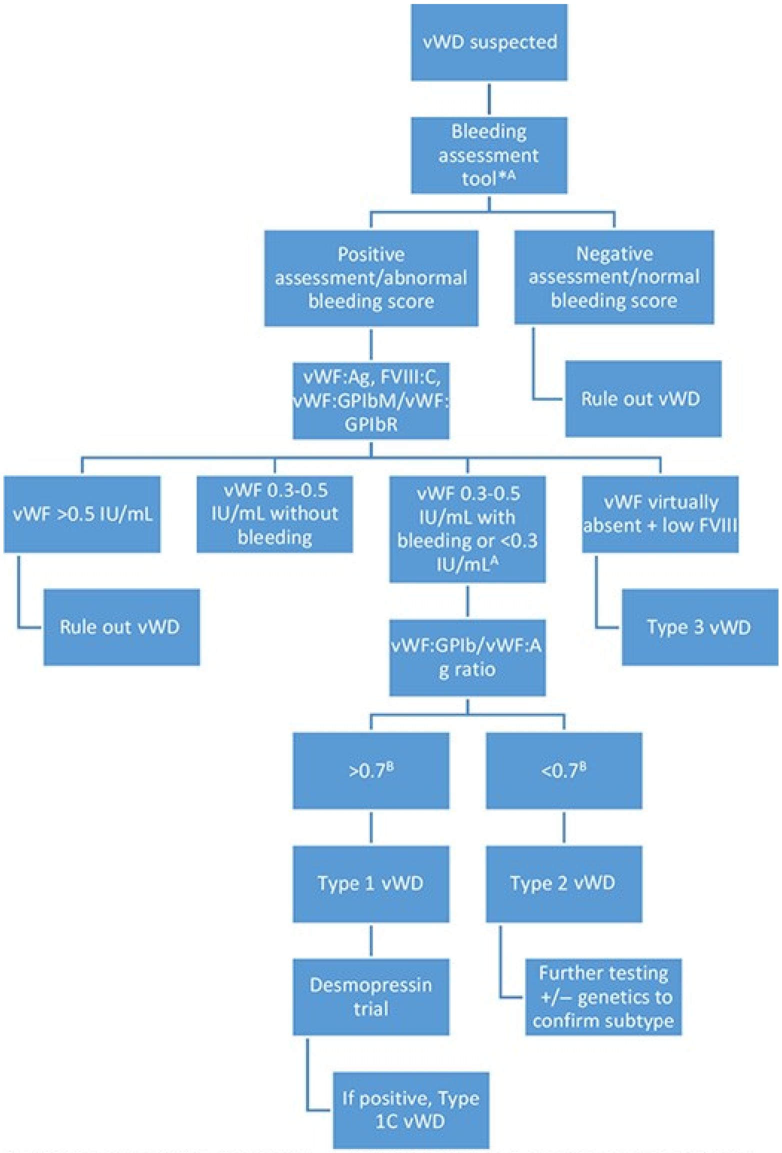
FIGURE 123-2

Classification and Diagnosis of vWD. *Patients with an intermediate or strong probability of vWD should not rely on bleeding assessment tools to guide blood specific testing.

Guideline recommendations:

A = Strong recommendation. Most individuals should follow the recommended course of action. Decision-making tools are not likely to be needed to help patients make decisions which align with their beliefs.

B = Conditional recommendation. Different choices will be appropriate for different patents. Decision aids may be helpful to ensure clinical management aligns with values, preferences, and acceptable risks. *(Adapted from James PD, Connell NT, Ameer B, et al. ASH ISTH NHF WFH 2021 guidelines on the diagnosis of vonWillebrand disease. Blood Adv. 2021;5(1):280–300.)*



vWD suspected
Bleeding assessment tool*A
Positive assessment/abnormal bleeding score
Negative assessment/normal bleeding score
vWF:Ag, FVIII:C, vWF:GPIbM/vWF:GPIbR
Rule out vWD
vWF >0.5 IU/mL
vWF 0.3-0.5 IU/mL without bleeding
vWF 0.3-0.5 IU/mL with bleeding or <0.3 IU/mLA
vWF virtually absent + low FVIII
Rule out vWD
vWF:GPIb/vWF:Ag ratio
Type 3 vWD
>0.7B
<0.7B
Type 1 vWD
Type 2 vWD
Desmopressin trial
Further testing +/− genetics to confirm subtype
If positive, Type 1C vWD

Type 1 vWD is the most common type, accounting for 70% to 85% of cases.[48,49] It is characterized by a mild-to-moderate quantitative reduction in the level of vWF (although its multimeric structure is normal) and a similar reduction in the level of factor VIII. It usually is inherited in an autosomal dominant fashion with variable penetrance and expression.[47] Bleeding symptoms often are very mild to moderate.[47] Patients with vWD can experience mucocutaneous bleeding, such as nosebleeds, bruising, gastrointestinal, or menstrual bleeding. Subjects may be at risk of bleeding following surgery, traumatic injury, or childbirth.[47] Type 1C vWD is characterized by increased clearance of vWF and may be identified by a desmopressin trial (preferred), or measuring the ratio of vWF propeptide to antigen.[45]

Type 2 vWD, diagnosed in 20% to 30% of affected patients, is characterized by a qualitative abnormality of vWF.[50] Bleeding manifestations may be more severe than with type 1 disease. Inheritance most often is autosomal dominant but may be recessive.[47] Type 2 vWD can be subdivided into four variants. Type 2A is the most frequent subtype and is characterized by a reduced vWF–platelet interaction and an absence of high- and intermediate-molecular-weight factor multimers. Type 2B is a less common variant characterized by an abnormal vWF that has an increased affinity for the platelet glycoprotein Ib receptor. This subtype is associated with thrombocytopenia, which is usually mild. In addition, high-molecular-weight forms of vWF are usually absent. A platelet-type pseudo-vWD has been characterized in which vWF is normal but a defect in the platelet glycoprotein Ib receptor causes an increased affinity for normal vWF.[47] As a result, platelet-type pseudo-vWD is phenotypically similar to type 2B disease but should be distinguished from it because the treatment is different. Type 2M arises from a qualitative defect in vWF that impairs its binding to platelets; it is similar to type 2A, except there is no measurable reduction in the high-molecular-weight multimers.[47] Finally, type 2N vWD (Normandy) is a rare form of the disease in which vWF has a markedly reduced affinity for factor VIII. This subtype leads to a moderate-to-severe reduction of factor VIII plasma levels with normal vWF levels.[47]

Type 3 vWD refers to a severe quantitative variant of the disease in which vWF is nearly undetectable and factor VIII levels are very low (<20 IU/dL [0.2 IU/mL]). Genetic defects in the vWF gene are null alleles in 80% of patients with type 3 disease, supporting the severe lack of vWF in this subtype.[50] Type 3 vWD is rare and accounts for less than 5% of all cases.[50] The clinical phenotype is severe, reflecting major deficits in primary hemostasis and coagulation.

Acquired von Willebrand Syndrome is a rare bleeding disorder that is similar to the congenital form of the disease. It is primarily associated with autoimmune disorders, such as systemic lupus erythematosus, lymphoproliferative disorders, myeloproliferative disorders, cardiovascular diseases, and certain neoplastic diseases, such as Wilms' tumor and lymphoma.[49] Certain medications have been associated with acquired vWD, most notably valproic acid, griseofulvin, and ciprofloxacin.[51,52] Bleeding manifestations vary from mild to severe, and the condition often resolves with treatment of the underlying disease. Various mechanisms have been proposed, including autoantibodies to vWF resulting in rapid removal from the plasma, adsorption to tumor cells or activated platelets, increased proteolysis, or mechanical destruction.[49]

Clinical Presentation and Diagnosis

CLINICAL PRESENTATION: Von Willebrand Disease

Signs and Symptoms

- Clinical manifestations are variable; some patients are asymptomatic
- Mucocutaneous bleeding: epistaxis, gingival bleeding with minor manipulation, menorrhagia
- Easy bruising
- Abnormal bleeding after surgery, childbirth, or dental procedures
- Severe cases: musculoskeletal bleeding

Two evidence-based guidelines regarding vWD were updated in early 2021; one focusing on diagnosis and the other on treatment (discussed later). The American Society of Hematology (ASH), the International Society on Thrombosis and Haemostasis (ISTH), the National Hemophilia Foundation (NHF), and the WFH formed a multidisciplinary panel to investigate and prioritize clinical questions and outcomes, assess current evidence, and make recommendations.[45]

When a patient has a lifelong history of mucocutaneous bleeding and a family history of abnormal bleeding, vWD should be suspected. A bleeding assessment tool (BAT) should be utilized as a screening measure to determine if a patient warrants specific blood testing for vWD. Many BATs exist, and there is not one recommended over another in the current guidelines.[45] Abbreviated examples of questions which may be included in a BAT are listed in Table 123-5. For patients with a low probability of vWD, such as those seen in a primary care setting, a BAT is recommended for initial screening. A positive bleeding assessment should determine specific blood testing over nonstandardized clinical assessment.[45] For patients with an intermediate probability of vWD eg, those referred to hematology; current guidelines recommend against relying on a BAT to determine specific blood testing for diagnosis.[45] Several different laboratory tests are helpful in the diagnosis of this hemostatic abnormality.

TABLE 123-5

Questions to Ask Patients—Bleeding Assessment Tools

Have you ever experienced epistaxis?

- If so, was it spontaneous?
- What interventions were required?
- When and how often did you experience these symptoms?

Have you ever experienced easy/frequent bruising, ecchymosis, or other cutaneous bleeding?

- If so, how often has this occurred?
- What medical interventions were required?
- Where was the location and size of the bleed?

Have you ever experienced prolonged bleeding from minor wounds?

- If so, did you require medical management? Please describe the intervention(s).

Have you ever experienced hematuria and/or gastrointestinal bleeding?

- If so, specify the type of bleeding (hematuria, melena, hematochezia, etc.)

Have you experienced bleeding in the oral cavity (gum bleeding, spontaneous or minor manipulation)?

- How often does this occur and when did it begin?
- Have you required medical management? If so, please describe.

Have you experienced menorrhagia?

- What medical intervention has been required?
- At what age did this symptom begin?

Have you experienced post-partum hemorrhage?

- How long after birth did this symptom occur?

Specific laboratory tests for the diagnosis of vWD include measurement of vWF antigen (vWF:Ag) level, factor VIII assay, determination of vWF ristocetin cofactor (vWF:RCo) activity, and vWF multimer analysis (see Table 123-4). Unfortunately, these levels vary considerably and often indeterminate or unreliable results can lead to confusion in the diagnosis. For example, the cutoff normal values for vWF:Ag, vWF:RCo, and other specialized tests vary between laboratories. This coupled with the natural variation of plasma concentrations of vWF can complicate interpretation of these results.[47] Plasma concentrations of vWF increase with age, stress, cigarette smoking, exercise, pregnancy starting in the second trimester, infection, and with the use of certain medications such as corticosteroids, high-dose estrogen oral contraceptives, and desmopressin. Repeated test measurements may be necessary due to this physiologic variability.[47]

Electroimmunoassay, immunoradiometric assay, or enzyme-linked immunosorbent assay, or ELISA, can be used to quantify vWF:Ag.[47] vWF:Ag levels are known to vary with different ABO blood types. Individuals with type O blood exhibit up to a 25% decrease in vWF levels when compared to those with type A due to increased plasma protein clearance.[47] The vWF:Ag level is usually low in types 1 and 2 vWD and virtually absent in type 3 disease. Factor VIII levels are normal or mildly decreased in patients with type 1 or 2 disease and very low (<10% [0.1 units/mL]) in those with type 3 disease.[47]

Ristocetin, an antibiotic that causes platelet aggregation in the presence of functional vWF, is used to measure vWF activity. The Ristocetin cofactor activity usually is reduced in parallel to vWF:Ag levels in types 1 and 3 disease and decreased to a greater extent than vWF:Ag in type 2 disease (except type 2B).[47] Low-dose ristocetin-induced platelet agglutination is useful for further distinguishing type 2B disease, as a low concentration of ristocetin induces excessive aggregation in type 2B disease.[47] When this measure in used, there is the potential for false results due to defects in vWF's ability to bind ristocetin due to genetic variants in the vWF gene.[48,54]

Newer, platelet-dependent assays are now recommended over the vWF:RCo activity test due to their lower coefficients of variation and higher reproducibility. Because glycoprotein Ib binding activity is reduced in most types of vWD, this measurement can guide diagnosis. The first assay functions independently of ristocetin and instead introduces gain-of-function mutations to GPIbα (glycoprotein Ib alpha); therefore, allowing it to bind vWF in vitro, spontaneously. The vWF:GPIbM assay provides greater precision with lower limits of detection compared to previous tests but is available.[48,55] Another assay still utilizes ristocetin, but also incorporates recombinant glycoprotein Ib fragments adhered to microparticles, rather than whole platelets. This assay may be susceptible to similar genetic variants as the vWF:RCo assay, however greater sensitivity and less variation has been observed.[54]

vWF, secreted as high-molecular-weight multimers, is cleaved in plasma to increasingly small protein fragments. The distribution of these multimer sizes can help determine the type of vWD. All multimer sizes are present in type 1 disease, whereas reduced levels of intermediate- and high-molecular-weight multimers are characteristic of type 2 disease. Patients with type 3 disease lack all sizes of vWF multimers. Molecular genetic testing for vWD is now a feasible option in some instances. Genetic testing may clarify diagnostic uncertainty that may remain after coagulation testing and clinical evaluation, and may be especially useful in diagnosing type 2B and 2N vWD.[45,47] Figure 123-2 illustrates the diagnostic algorithm recommended by the guidelines for types 1 and 2 vWD. Type 3 vWD is not addressed in the most recent guidelines, as diagnosis is relatively straight forward for these patients. vWF is virtually absent in type 3 disease (<3 IU/dL [0.03 IU/mL]), with an associated low FVIII level.

Treatment: von Willebrand Disease

6 The specific type of vWD and the location and severity of bleeding determine the approach to treatment. The guidelines from ASH, ISTH, NHF, and WFH cover recommendations ranging from prophylaxis in severe disease to heavy menstrual bleeding.[53] The comprehensive care of patients with vWD requires an interprofessional team approach. The desired outcome is to prevent bleeding episodes and their short-term and long-term consequences so that patients with vWD can live active and productive lives. Local measures, including prolonged pressure, ice, and topical thrombin, often can control superficial bleeding. Systemic treatment is used for bleeding that cannot be controlled in this manner and for the prevention of bleeding with surgery. The goal of systemic therapy is to correct platelet adhesion and coagulation defects by stimulating the release of endogenous vWF or by administering products that contain vWF and factor VIII or vWF alone.[53] General guidelines for the treatment of vWD are shown in Table 123-6.

TABLE 123-6

Management Recommendations—ASH–ISTH–NHF–WFH Guidelines

Clinical Question	Recommendation	Strength of Recommendation
Prophylaxis	In vWD with severe and frequent bleeds, long-term prophylaxis is suggested, rather than no prophylaxis.	Conditional
Desmopressin Trial and administration	If desmopressin in an option (primarily Type 1) and vWF <0.30 IU/mL, trial of desmopressin is suggested. The panel suggests against treating with desmopressin in the absence of a trial first.	Conditional
Antithrombotic Therapy	In patients with vWD and cardiovascular disorders requiring anticoagulants or antiplatelet agents, use of these agents is suggested over no therapy.	Conditional
Major surgery	Target vWF and FVIII activity levels ≥0.50 IU/mL for at least 3 days after surgery.	Conditional
Minor surgery/invasive procedures	Target vFW activity levels ≥0.50 IU/mL using desmopressin or factor concentrate along with tranexamic acid.	Conditional
Gynecology—heavy menstrual bleeding	Hormonal therapy or tranexamic acid is suggested over desmopressin.	Conditional

Abbreviated recommendations from the 2021 Guidelines on treatment of vWD. Additional recommendations can be found in the source document. Strength of Recommendations: *Strong:* Most individuals should follow the recommended course of action. Decision-making tools are not likely to be needed to help patients make decisions which align with their beliefs. *Conditional*: Different choices will be appropriate for different patents. Decision aids may be helpful to ensure clinical management aligns with values, preferences, and acceptable risks. (*Data from Reference* 53.)

Replacement Therapy

⑦ The treatment of choice for patients with severe vWD, including types 2B, 2M, and 3 vWD and for patients with type 1 or 2A vWD who are unresponsive to desmopressin, is replacement therapy with vWF concentrate.[53] Several virus-inactivated, intermediate- or high-purity plasma-derived factor VIII concentrates contain sufficient amounts of functional vWF for treatment in this patient population (see Table 123-2). Ultrahigh-purity (monoclonal antibody-derived) plasma-derived products contain only negligible amounts of vWF and recombinant factor VIII products contain no vWF and are inadequate for treatment of vWD. The evolution of replacement therapy over the past several decades has improved the therapy options available to patients, particularly with severe disease.[56]

Recombinant vWF alone was approved by the US Food and Drug Administration (FDA) in 2015 for on-demand treatment and control of bleeding episodes as well as perioperative management of bleeding in patients with vWD. Unlike plasma-derived vWF, recombinant products have no exposure to the ADAMTS13 (a disintegrin and metalloprotease with thrombospondin type 1 motif, member 13) which cleave large multimers.[57] Ultralarge and high-molecular-weight multimers are necessary for optimal platelet plug formation, making recombinant products ideal.[56,57]

Cryoprecipitate was one of the earliest forms of replacement therapy for vWD. It contains about 80 to 100 units of vWF per unit (5-10 times more vWF and factor VIII than fresh-frozen plasma), and it was the mainstay of therapy for vWD. However, because cryoprecipitate is not always virally inactivated, it should not be used as first-line treatment and is no longer recommended in the United States or Europe.[56]

Other Pharmacological Therapy

⑧ Desmopressin stimulates the endothelial cell release of vWF and factor VIII. It is temporarily effective for patients with vWD who have adequate endogenous stores of functional vWF, which includes most patients with type 1 disease and some patients with type 2A disease. Conversely, desmopressin is not appropriate for patients with type 3 disease, who lack stores of vWF. Desmopressin usually is not recommended for the treatment of type 2B disease because the release of additional abnormal vWF may exacerbate thrombocytopenia, but it has been reported to be beneficial in some patients with type 2B disease.[58] If desmopressin is used for the treatment of type 2B disease, close monitoring is necessary.

The dose of desmopressin used for treatment of vWD is identical to that used for treatment of mild factor VIII deficiency, 0.3 mcg/kg given IV over 15 to 30 minutes.[15] Patients with vWD generally have a better response to desmopressin than those with hemophilia, with an average three- to fivefold increase in vWF and factor VIII levels.[48] These levels remain elevated for about 6 to 8 hours. The response to desmopressin in a given patient usually is consistent, and a desmopressin trial should determine if the medication likely will be effective for the individual. Desmopressin is preferable to use of plasma-derived products for patients who have an adequate response because desmopressin does not carry a risk of viral transmission. An added benefit is the substantially lower cost of desmopressin compared to the plasma-derived and recombinant products. (For a discussion of the adverse drug reactions of desmopressin, see “Hemophilia: Other Pharmacologic Therapy section.)

Desmopressin can be administered every 12 to 24 hours, but the response diminishes with repeated treatment. After three to four doses, desmopressin often is no longer effective and alternative replacement therapy may be necessary if prolonged treatment is required. Laboratory monitoring, including vWF:Ag measurements, factor VIII assays, vWF:activity assessments, and clinical examinations, will determine the adequacy of treatment.[58] Intranasal administration of desmopressin, at the same dosage as that used for mild factor VIII deficiency, can be useful for the treatment of mild bleeding episodes. One or two doses administered at the start of menses may help control menorrhagia. Oral contraceptives may also be very effective in controlling this symptom (see Table 123-6). Antifibrinolytic agents, such as aminocaproic acid and tranexamic acid, may be of special value in bleeds associated with tissues rich in plasminogen activators, such as the mouth, especially with tooth extractions.[58] These agents can also be used in the management of epistaxis, GI bleeding, and menorrhagia. However, these agents should be avoided in urinary tract bleeding because of the risk of thrombosis and obstruction.

In acquired vWD, low levels of plasma vWF are the result of accelerated removal of protein from plasma through the action of different pathogenic mechanisms. Acquired vWD may be associated with monoclonal gammopathy, lymphoproliferative or myeloproliferative syndromes, or autoimmune disorders. Cardiovascular disease, such as aortic stenosis and congenital cardiac defects, are increasing in the literature as causes of acquired vWD. Intravenous immune globulin remains a therapeutic option in acquired vWD, along with vWF concentrate and/or desmopressin.[51]

Gene Therapy

Patients with the most severe bleeding phenotypes of vWD (type 3 and some severe cases of types 1 and 2) may be the most likely candidates for gene therapy, which offers the potential of a long-term, if not lifelong, correction of vWF deficiency. Preclinical trials are being conducted to test the feasibility of gene transfer in the management of vWD.[59]

Evaluation of Therapeutic Outcomes

Since the main goal in the treatment of vWD is to prevent or control bleeding and the consequences of such bleeding, bleeding episodes can be monitored via clinical and laboratory parameters. Monitoring the number and types of bleeding episodes and measurement of plasma concentrations of vWF and factor VIII make it possible to evaluate the effectiveness of specific prophylactic and treatment regimens. As with hemophilia patients, assessment of patients’ activities of daily living gives clinicians a better appreciation of the success of the treatment plan.

OTHER CONGENITAL FACTOR DEFICIENCIES

Rare bleeding disorders constitute 3% to 5% of all inherited coagulation factor deficiencies.[60] These rare bleeding disorders include congenital deficiencies in fibrinogen, in factors II, V, VII, X, XI, and XIII, and in combinations of factor deficiencies. Contact factor abnormalities, including deficiencies in factor XII, high-molecular-weight kininogen, and prekallikrein, prolong the aPTT but do not lead to any bleeding diathesis. Identification of these disorders is important so that inappropriate treatment is not given. The only contact factor deficiency associated with bleeding symptoms is factor XI deficiency. Also known as hemophilia C, this deficiency is particularly common in people of Ashkenazi Jewish descent.[61] Bleeding manifestations are variable. Bleeding usually does not occur spontaneously, but excessive bleeding may occur after trauma or surgery. Most other deficiencies are inherited as autosomal recessive disorders and are rare. Some patients with abnormal molecules, such as a dysfibrinogenemia, may have an increased tendency to develop thromboembolic disease. Most of these deficiencies are treated with fresh-frozen plasma. Newer specific concentrates are becoming available. For example, a factor XIII plasma-derived concentrate is available, and recombinant factor VIIa is approved for use in patients with congenital VII deficiency. Cryoprecipitate, which is rich in fibrinogen, or fibrinogen concentrates (RiaSTAP®), can be used to treat patients with fibrinogen deficiency or dysfunctional fibrinogen (dysfibrinogenemia).

COMPLICATIONS OF REPLACEMENT THERAPY

As discussed previously, the transmission of blood borne infectious diseases is a concern when blood and blood-derived products are used. Most patients with hemophilia who received plasma-derived products were infected with hepatitis viruses and HIV during the 1980s prompting the development of viral inactivation methods for use during the manufacturing of factor concentrates.[15] All available plasma-derived factor concentrates come from screened donors and undergo viral inactivation procedures in an effort to reduce the risk of viral transmission. Heat treatment, which includes dry and wet heat, is one method of viral inactivation. Wet heat is applied while the concentrate is in suspension or in solution (pasteurization) and is more effective than dry heat. Other methods of viral inactivation include chemical (solvent detergent) and affinity chromatography with monoclonal antibodies. Solvent detergent treatment inactivates lipid-coated viruses, such as HIV and hepatitis B and C, but it is not effective against parvovirus B19, transfusion transmitted virus, hepatitis A, or prions.[5] Parvovirus B19 is found in both plasma-derived and recombinant factor VIII concentrates (due to the use of albumin as a stabilizer in some recombinant products).[5,19] Parvovirus B19 may be particularly important for patients with hemophilia and HIV infection because it can cause chronic anemia in patients with immune deficiency.

Other complications associated with factor administration include allergic reactions, fever, chills, urticaria, and nausea. PCCs and aPCCs also have the potential to cause thromboembolic complications, including deep-vein thrombosis, pulmonary embolism, myocardial infarction and disseminated intravascular coagulation, likely related to the presence of activated factors.[15] Antifibrinolytic agents should not be given to patients receiving PCCs or aPCCs to avoid thrombotic complications.

Porcine factor VIII, used in the treatment of patients with inhibitors to factor VIII, is not known to transmit human viruses. However, allergic-type reactions (eg, fever, chills, skin rashes, nausea, and headaches) have been reported.[15] Patients who experience these reactions can be treated with steroids and/or diphenhydramine. Thrombocytopenia is another potential complication of porcine factor VIII use.[15]

CONCLUSION

Coagulation disorders, such as hemophilia and vWD, affect a small subset of the overall population, but their treatment can be costly and complicated, requiring knowledgeable health professionals and an interprofessional team approach for optimal outcomes to be achieved. Exciting progress is being made in the development of new strategies for treating these types of disorders. The development of new factor products with improved pharmacokinetic properties, non-factor replacement therapy, as well as the advances in gene therapy may soon redefine the therapeutic landscape for these patients and improve their overall experience.

ABBREVIATIONS

AAV	adeno-associated virus
ADAMTS13	a disintegrin and metalloprotease with thrombospondin type 1 motif, member 13
aPCC	activated prothrombin complex concentrate
aPTT	activated partial thromboplastin time
ASH	American Society of Hematology
BAT	bleeding assessment tool
BU	Bethesda unit
cDNA	circulating DNA
HIV	human immunodeficiency virus
IgG	immunoglobulin G
ISTH	International Society on Thrombosis and Haemostasis
ITI	immune tolerance induction
NHF	National Hemophilia Foundation
NSAID	nonsteroidal anti-inflammatory drug
PCC	prothrombin complex concentrate
PRICE	Protect, Rest, Ice, Compression, and Elevation
SIPPET	Survey of Inhibitors in Plasma-Product Exposed Toddlers
vWD	von Willebrand disease
vWF	von Willebrand factor
vWF:Ag	von Willebrand factor antigen
vWF:RCo	von Willebrand factor ristocetin cofactor
vWF:GPIbM	von Willebrand factor glycoprotein Ib mutational assay

SELF-ASSESSMENT QUESTIONS

1. The genetic inheritance pattern for hemophilia is:
    A. Autosomal dominant and more prevalent in males
    B. Autosomal recessive and more prevalent in females
    C. X-linked, therefore affects more females than males
    D. X-linked, therefore affects more males than females
2. The factor deficit in hemophilia B is:
    A. Factor II
    B. Factor VII
    C. Factor VIII
    D. Factor IX
3. Standard of care for patients with severe hemophilia A consists of:
    A. Desmopressin therapy to treat bleeding episodes
    B. Regular administration of a hemostatic agent(s) to prevent bleeding episodes
    C. Administration of activated prothrombin complex concentrates in all patients with active bleeds
    D. On-demand factor therapy to avoid long-term complications
4. Patients with moderate hemophilia have _____ factor activity level.
    A. 1% to 5% (0.01 to 0.05 units/mL)
    B. 1% to 10% (0.01 to 0.1 units/mL)
    C. 5% to 10% (0.05 to 0.1 units/mL)
    D. 10% to 40% (0.1 to 0.4 units/mL)
5. The first-line therapeutic approach to treat an active bleed in a patient with severe hemophilia *with* inhibitors is:
    A. Low-dose factor replacement for patients with low titer inhibitors
    B. Recombinant factor VIII replacement for patients with any level of inhibitors
    C. Activated prothrombin complex concentrates (aPCCs) for patients with high titer inhibitors

D. Alternating desmopressin and anti-thrombolytics in any patient with inhibitors

6. Which of the following is a *true* statement regarding prophylaxis therapy for hemophilia?

   A. Not recommended by any national organization.

   B. Recommended approach but optimal dosing and schedule is not well defined.

   C. Proven cost effective.

   D. Patient compliance is not a factor in overall outcome.

7. What is the mechanism by which activated prothrombin complex concentrates (aPCCs) overcome inhibitors?

   A. aPCCs provide multiple factor products which are known deficits in hemophilia.

   B. Vitamin K-dependent factors and small quantities of activated factor products in aPCCs overcome most inhibitor titers.

   C. aPCCs provide factor products which bypass the antibodies that inhibitors target.

   D. Large concentrations of factor IX and VIII are present in aPCCs and are able to overcome inhibitors.

8. Which of the following is *true* regarding emicizumab?

   A. Approved for use in adults with severe hemophilia

   B. Acts as a bridge between activated factor IX and factor X

   C. Proven effective only in pediatric patients without inhibitors

   D. Given subcutaneously one time per month

9. Select the appropriate approach to treating an acute bleed in a patient with hemophilia A with the corresponding inhibitor titer:

   A. 8 BU/mL; High dose plasma derived FVIII

   B. 7 BU/mL; Activated prothrombin complex concentrates

   C. 6 BU/mL; High dose recombinant FVIII

   D. <5 BU/mL; Activated prothrombin complex concentrates

10. 10. Though target ranges differ based on risk and clinical status, what is the ideal factor activity level for a patient undergoing a surgical procedure?

   A. >5% (>0.05 units/mL)

   B. 5% to 40% (0.05 to 0.4 units/mL)

   C. 40% to 70% (0.4 to 0.7 units/mL)

   D. 50% to 100% (0.5 to 1.0 units/mL)

11. How much does 1 unit/kg of plasma-derived factor IX increase the factor activity level in a patient with hemophilia B?

   A. <1% (<0.01 units/mL)

   B. 1% (0.01 units/mL)

C. 2% (0.2 units/mL)

D. 50% (0.5 units/mL)

12. What would be the appropriate dose of recombinant factor IX for an adult patient with severe hemophilia B requiring a 50% correction?

A. 25 units/kg

B. 50 units/kg

C. 60 units/kg

D. 70 units/kg

13. Which of the following is a common presentation of von Willebrand disease?

A. Bleeding of the gums after major procedures only

B. Keratoconjuntivitis sicca

C. Delayed bruising

D. Menorrhagia

14. Which of the following factor products can be used to treat severe bleeding episodes in patients with von Willebrand disease?

A. Recombinant von Willebrand factor

B. Recombinant FVIII

C. Plasma-derived FVIII

D. Desmopressin

15. Which of the following is a *true* statement regarding desmopressin?

A. Desmopressin is effective in patients with severe hemophilia A.

B. Desmopressin is effective in patients with severe hemophilia B.

C. Desmopressin exhibits tachyphylaxis with repeated dosing.

D. Desmopressin is effective in all patients with von Willebrand disease.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** Both hemophilia A and B are recessive, X-linked diseases, resulting in a higher incidence in males (see “Hemophilia” section).

2. **D.** Hemophilia B, also known as Christmas disease, is the result of a deficiency in factor IX (see “Hemophilia” section).

3. **B.** Prophylaxis is recommended in severe hemophilia, as it reduces bleeding episodes and damage due to recurrent joint bleeds. The agents used for prophylaxis has traditionally been factor concentrates; however, products like emicizumab have helped create a modern definition of prophylaxis (see “Prophylaxis Using Factor Replacement” and “Prophylaxis with Non-factor Products” sections)

4. **A.** Moderate hemophilia is defined as factor activity level of 1% to 5% (0.01 to 0.05 units/mL)(see “Hemophilia” section for clinical manifestations).

5. **C.** Patients with low titer inhibitors may be treated with high-dose factor replacement therapy, while patients with high titer inhibitors require agents

that bypass the factor to which the antibody has formed (see "Treatment of Inhibitors" subsection under "Hemophilia" section and Fig. 123-2).

6. **B.** There is not strong literature to support the dosing and timing of initiation of prophylactic factor therapy. Though primary prophylaxis is an expensive approach, the WFH does recommend it in patients with severe hemophilia. Ideal hemostatic agents used for prophylaxis is becoming more inclusive with regard to mechanisms of action and modalities of administration. (See "Prophylaxis Using Factor Replacement" and "Prophylaxis with Non-factor Products" sections.)

7. **C.** Activated prothrombin complex concentrates (aPCCs) contain greater quantities of activated factor products (namely factor X and prothrombin) which are able to bypass the factor to which the antibody is directed (see "Treatment of Inhibitors" subsection under "Hemophilia" section).

8. **B.** Emicizumab performs the function of activated factor VIII by bridging activated factor IX and factor X (see "Treatment of Inhibitors" subsection under section "Hemophilia" section).

9. **B.** Patients with inhibitor titers <5 BU/mL can generally be treated with high-dose factor replacement therapy. Patients with titers >5 BU/mL require bypassing agents, such as aPCCs (see "Treatment of Inhibitors" subsection under "Hemophilia" section and Fig. 123-1).

10. **D.** The dose of replacement factor required perioperatively will differ between patients. Ideally, the patient's factor activity level should be maintained at 50% to 100% (0.5 to 1.0 units/mL) depending on clinical status and type of procedure (see "Surgery" subsection under "Hemophilia" section and Table 123-3).

11. **B.** For plasma-derived factor IX, each unit/kg of factor results in an increase of about 1% (0.01 units/mL) in the plasma factor activity level. Calculations for recombinant factor products in pediatric and adult patients contain specific multipliers due to the lower recovery of recombinant products compared to plasma-derived products (see "Factor IX Dosing" section).

12. **C.** Use the following equation for adult patients: Recombinant factor IX (units) = (Desired level − Baseline level) × 1.2 × (Weight [in kilograms]) ⟶ 60 units/kg = (50%-0%) × 1.2 (see "Factor IX Dosing" section).

13. **D.** Some patients with von Willebrand disease are asymptomatic. If patients do have symptoms, they often present with mucocutaneous bleeding, menorrhagia, easy bruising, and postoperative bleeding (see "von Willebrand Disease" section and its "Clinical Presentation" subsection).

14. **A.** Recombinant vWF was approved for on-demand treatment and control of bleeding episodes in patients with vWD. While plasma-derived FVIII concentrates contain sufficient amounts of vWF to treat bleeding episodes, recombinant products contain no vWF and are inadequate for treatment (see "Replacement Therapy" subsection under "von Willebrand Disease" section).

15. **C.** Tachyphylaxis occurs on repeated dosing of desmopressin. This drug is not effective in patients with severe hemophilia and some forms of von Willebrand disease (see "Hemophilia," "Other Pharmacologic Therapy," and "von Willebrand Disease" sections).

Chapter 124: Sickle Cell Disease

Jin Han; Santosh L. Saraf; Victor R. Gordeuk

KEY CONCEPTS

KEY CONCEPTS

① Sickle cell disease is an inherited disorder caused by a defect in the gene for β-globin, a component of hemoglobin. It is considered to be a qualitative hemoglobinopathy. Patients can have one defective gene (sickle cell trait) or two defective genes (sickle cell disease).

② Although sickle cell disease usually occurs in persons of African ancestry, other ethnic groups can be affected. Multiple mutation variants are responsible for differences in clinical manifestations.

③ Sickle cell disease involves multiple organ systems. Usual clinical signs and symptoms include anemia, pain, splenomegaly, and pulmonary symptoms. Sickle cell disease is diagnosed through routine newborn screening programs available in all 50 states. Early diagnosis allows early preventive and comprehensive care.

④ Patients with sickle cell disease are at risk for infection. Prophylaxis against pneumococcal infection reduces death during childhood.

⑤ Hydroxyurea decreases the risk of painful episodes, but patients treated with hydroxyurea require careful monitoring.

⑥ Neurologic complications caused by vasoocclusion and hemolysis can lead to stroke. Screening with transcranial Doppler ultrasound to identify children at risk accompanied by chronic transfusion therapy programs can decrease the risk of overt and silent stroke in children with sickle cell disease.

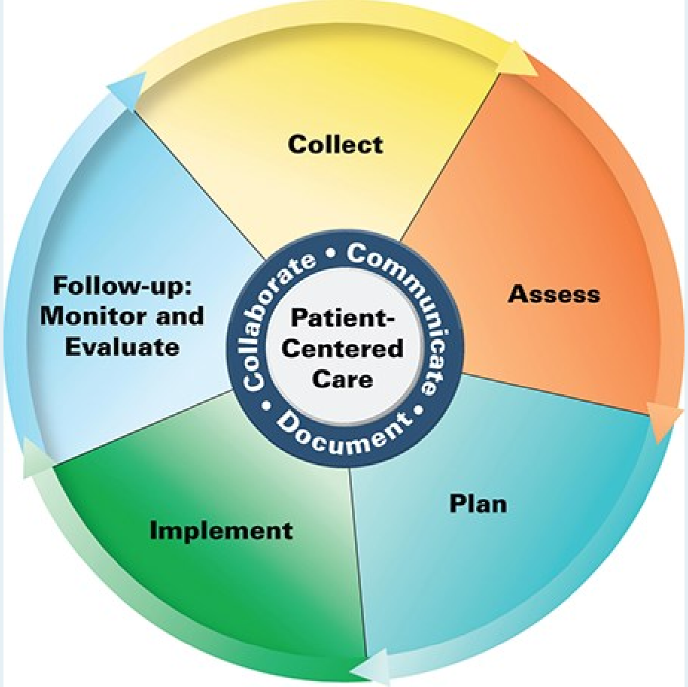
⑦ Patients with fever greater than 38.5°C (101.3°F) should be evaluated, and appropriate antibiotics administered immediately, including coverage for encapsulated organisms, especially pneumococcal organisms.

⑧ Pain episodes can often be managed at home. Hospitalized patients require parenteral analgesics. Analgesic options include opioids, nonsteroidal anti-inflammatory agents, and acetaminophen. The patient characteristics and the severity of the pain should determine the choice of agent and regimen.

⑨ Patients with sickle cell disease should be followed regularly for healthcare maintenance issues and monitored for changes in organ function.

PATIENT CARE PROCESS

Patient Care Process for Vasoocclusive Episodes



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, sickle cell disease genotypes)
- Patient medical history (include organ function and psychosocial issues)
- Immunization history
- Social history (eg, tobacco use)
- Pain diary
- Medication use
- Blood transfusion history
- Objective data
    - Vital signs: blood pressure, heart rate, respiratory rate, height, weight, O_2 saturation
    - Labs: complete blood count (CBC), reticulocytes, basic chemistry, lactate dehydrogenase, ferritin, urine analysis, hemoglobin fractionation
    - Additional labs or imaging per presenting symptoms (see Table 124-2)

Assess

- Hemodynamic stability
- Pain scale
- Adherence to home medication
- Sign or symptom associated with sickle cell acute complications (see Table 124-2)

Plan*

- Fluid
- Pain management (see Table 124-6)
- Initiate antibiotics if febrile
- Oxygen

Implement

- Provide education on current pain regimen
- Develop individualized plan for pain management
- Evaluate for initiation of hydroxyurea, L-glutamine, voxelotor, crizanlizumab
- Schedule follow-up

Follow-up: Monitor and Evaluation

- Ongoing evaluation of pain level
- Monitor for adverse drug reactions of pain medication and initiate supportive care if needed

**Collaborate with patients, caregivers, and other healthcare professionals.*

INTRODUCTION

① Sickle cell syndromes, which can be divided into sickle cell trait (SCT) and sickle cell disease (SCD), are a group of hereditary conditions characterized by the presence of sickle cell hemoglobin (HbS) in red blood cells (RBCs). SCT is the heterozygous inheritance of one normal β-globin gene producing hemoglobin A (HbA) and one sickle gene, producing HbS (HbAS). Individuals with SCT are usually asymptomatic. SCD can be of homozygous or compounded heterozygous inheritance. Homozygous HbS (HbSS) has historically been referred to as sickle cell anemia (SCA), which now also includes HbSβ^0-thal due to similarities in clinical severity. The heterozygous inheritance of HbS with another qualitative or quantitative β-globin mutation results in sickle cell hemoglobin C (HbSC), sickle cell β-thalassemia (HbSβ$^+$-thal and HbSβ^0-thal), and some other rare phenotypes.[1-4]

Over the years, progress has been made in our understanding of the relationship between clinical severity and genotype, as well as the pathological cascades leading to complications and morbidities associated with SCD. Ongoing research focuses on disease modification, organ damage prevention, and curative treatment. Advances in the care of patients with SCD have increased life expectancy to adulthood. Therefore, the transition from pediatric to adult medical care has become a focus to further improve survival and quality of life.[1-7]

SCD is a chronic illness with financial and emotional challenges for patients and their caregivers and high economic impact on society. Frequent hospitalizations can interrupt schooling and result in employment difficulties.[8,9] Acute complications of the disease can be unpredictable, rapidly progressive, and life-threatening. Later in life, chronic organ damage and cognitive or emotional impairment can develop.[3,7,10,11] Because of the complexity of the illness, comprehensive care must be available to all patients and that all providers have a good understanding of disease progression and management.[1,10,11]

EPIDEMIOLOGY

② SCD affects millions of people worldwide. The condition is most common in people with African heritage.[2,3] The most common SCD genotype is HbSS (60%-65%), followed by HbSC (25%-30%), HbSβ^+-thal, and HbSβ^0-thal (5%-10%). Other variants account for less than 1% of patients.[1,2,5] The prevalence of SCD is highest in sub-Saharan Africa. The sickle mutation can also be found in the Arabian Peninsula, the Indian subcontinent, and the Mediterranean region.[1,3-5] An estimated 300,000 children are born each year with SCD-HbSS and another 50,000 to 100,000 births per year for other forms of SCD.[8] In the United States, about 100,000 Americans have SCD with a prevalence of 1 in 2,500 newborns of all ethnicities, 1 in 365 Black births, and 1 in 36,000 Hispanic births.[1,5]

The prevalence of SCD in a region is determined by the frequency of SCT. An estimated 300 million people are carriers worldwide.[12] The distribution of SCT reflects the survival advantage in regions where malaria is endemic as the gene mutation offers partial protection against serious malarial infection. Since RBCs carrying the abnormal sickle hemoglobin (Hb) prevent the normal growth and development of *Plasmodium falciparum* within RBCs, individuals with SCT are more likely to survive an acute malarial illness.[13] The overall incidence of SCT reported in the United States is 15.5 per 1,000 newborns, with a rate of 7.3% in Black, 0.6% in Hispanics, and 0.3% in White.[14,15]

ETIOLOGY

Normal hemoglobin (HbA) is composed of two α-chains and two β-chains ($\alpha_2 \beta_2$). The biochemical defect that leads to the development of HbS involves the substitution of valine for glutamic acid as the sixth amino acid in the β-polypeptide chain. Another abnormal hemoglobin, hemoglobin C (HbC), is produced by the substitution of lysine for glutamic acid as the sixth amino acid in the β-chain. Structurally, the α-chains of HbS, HbA, and HbC are identical. Therefore, it is the chemical differences in the β-chain that account for sickling and its related sequelae.[1-4]

Homozygous HbSS, the most common form of SCD, occurs when an individual inherits both maternal and paternal β-globin alleles that code for HbS. Figures 124-1 to 124-4 show the probability of inheritance with each pregnancy for the offspring of parents with HbA, SCT, and HbSS. β-Thalassemia is a quantitative hemoglobinopathy resulting from a genetic defect in β-globin production that may vary from no β-globin production (β^0) to some β-globin production (β^+). β-Thalassemia can be co-inherited with HbS. Individuals with HbSS and HbSβ^0-thal have a more severe course than those with HbSC and HbSβ^+-thal and are now both referred to as SCA.[2,4,10]

SCD is most commonly found among people with ancestors from sub-Saharan Africa, India, Saudi Arabia, and Mediterranean countries. Genetic analysis shows that the haplotype containing the sickle mutation found in Arabic patients differs from the haplotype in those of African descent. These haplotype variants associated with different geographic regions may be responsible for variations in the clinical manifestations and response to therapy.[1-3,7] The three most common haplotypes in the United States are the Bantu haplotype, characterized by severe disease; the Senegal haplotype, characterized by mild disease; and the Benin haplotype, characterized by a course intermediate to that of the other two haplotypes. Although there are a number of other haplotypes seen around the world, the major types outside of the United States are found in Saudi Arabia and Cameroon, both with milder courses of illness.[1-3,7,10,16] Other genetic modifiers such as coincident a-thalassemia and the levels of fetal hemoglobin concentration also affect the clinical severity of SCD.[1]

PATHOPHYSIOLOGY

Normal adult RBCs contain predominantly HbA (96%-98%). Other forms of Hb are HbA_2 (2%-3%) and fetal Hb (<1%). Normal RBCs have a biconcave shape and are able to deform to squeeze through capillaries. Fetal hemoglobin (HbF) is a tetramer of two α-globin chains and two γ-globin chains ($\alpha_2\gamma_2$) that is present predominantly in fetal RBCs.[2,3,7,13] Prior to birth, HbF is the predominant Hb type. At around 32-week gestation, a switch from the production of γ chains to β-chains occurs and consequently an increase in HbA production occurs. Increased HbF production occurs under severe erythroid stress, such as anemia, after hematopoietic stem cell transplantation (HSCT) or chemotherapy, or in the hereditary condition, hereditary persistence of fetal hemoglobin (HPFH), where a mutation in the β-globin gene cluster results in continued HbF production after birth. HPFH is a benign, asymptomatic condition.[2,3,17] HbF does not participate in the formation of the HbS polymer, so its presence in the HbSS RBC in sufficient quantity can prevent the sickling phenomenon described below.

In the pathogenesis of SCD, the following are responsible for the various clinical manifestations: impaired circulation, destruction of RBCs with release of RBC content to the plasma, stasis of blood flow, and ongoing inflammatory responses. These changes result directly from two major disturbances involving RBCs: abnormal Hb polymerization and membrane damage (Fig. 124-5).

The solubilities of HbS and HbA are the same under conditions of normal oxygenation, but the solubility of deoxygenated HbS is reduced because of the valine substitution. Deoxy-HbS leads to intermolecular binding and formation of thin bundles of fibers, which initially are unstable. However, the increased binding of deoxy-HbS eventually results in cross-linked fibers and stable polymers. This process is influenced by mean corpuscular Hb concentration, temperature, intracellular pH, and the circulating amount of HbS. Polymerization allows deoxygenated Hb molecules to exist as a semisolid gel that protrudes into the cell membrane, leading to distortion of RBCs (sickle shaped) and loss of deformability. The presence of sickled RBCs increases blood viscosity and encourages sludging in the capillaries and postcapillary venules. Such obstructive events lead to local tissue hypoxia, which tends to accentuate the pathologic process.[4,18,19]

When reoxygenated, polymers within the RBCs disassemble and the RBCs eventually return to normal shape. This process contributes to vasoocclusion because the HbS-containing RBCs are able to enter the microvasculature when oxygenated, but sickle as Hb releases oxygen to the tissues. The cycle of sickling and unsickling results in damage to the cell membrane, loss of membrane flexibility, and rearrangement of surface phospholipids. Membrane damage also alters ion transport, resulting in potassium and water loss, which can lead to a dehydrated state enhancing the formation of sickled forms. After continual repetitions of the process, the RBCs develop into rigid irreversibly sickled cells (ISCs). Unlike the reversible sickled cells, which have normal morphology when oxygenated, ISCs are elongated cells that remain sickled when oxygenated. The more rigid membranes of these ISCs retard flow, particularly through the microcirculation. In addition, sickled RBCs tend to adhere to vascular endothelial cells, which further increases polymerization and obstruction.[1,6,18,19]

Intermolecular binding and polymer formation are reduced by HbF and to a lesser degree by HbA_2. RBCs that contain HbF sickle less readily than cells without. ISCs, not surprisingly, have a low HbF level. Increased levels of HbF, as in the case of the Saudi Arabian haplotype, result in a more benign form of SCD. The amount of HbF and HbA_2 in relation to HbS influences the clinical manifestations and accounts for some of the variability in severity among SCD genotypes.[2,3,5]

Intravascular destruction of sickle cells occurs at an accelerated rate. The stress of repetitive sickle–unsickle cycles leads to damage to the cell membrane that promotes recognition and removal of the damaged RBCs by macrophages. Rigid ISCs are easily trapped, resulting in short circulatory survival and chronic hemolysis. The typical sickle cell survives for about 10 to 20 days, while the life span of a normal RBC is 120 days.[7,10] Anemia triggers the release of immature RBCs (reticulocytes) from the bone marrow prematurely. Surface adhesion proteins of reticulocytes adhere to the endothelium in postcapillary venules, further decreasing the movement of mature HbS-containing RBCs through the microvessels.[1-3]

SCD is a complex disease of inflammation as evidenced by leukocytosis, particularly an increase in monocytes and neutrophil counts. Coagulation abnormalities in SCD are the result of continuous activation of the hemostatic system or disorganization of the membrane layer. Sickled cells interact with leukocytes, endothelial cells, and platelets to form an occlusive clot. Hemolysis releases free Hb resulting in generation of reactive oxygen species, nitric oxide (NO) depletion, and vascular inflammation. Chronic NO depletion contributes to vasoconstriction, activation of platelets and adhesion molecules such as vascular cell adhesion molecule 1 and production of the potent vasoconstrictor peptide endothelin-1.[2,3,6,13,20]

Obstruction of blood flow in the spleen by sickle cells can result in functional asplenia, defined as the loss of splenic function with an intact spleen, and eventually splenic atrophy. These patients can have deficient opsonization. Impaired splenic function increases susceptibility to infection by encapsulated organisms, particularly pneumococcal bacteria.[1,5,13]

CLINICAL PRESENTATION

③ Since 2006, universal newborn screening for SCD is performed in all 50 states. The sensitivity and specificity of screening methods such as isoelectric focusing, high-performance liquid chromatography, and Hb electrophoresis approach 100%. For infants with a positive screening result, a second test should be performed before 2 months of age to confirm the diagnosis. More than 98% newborns in the United States are screened for SCD. Some infants with SCD may not be identified because of extreme prematurity, prior blood transfusion, inability to contact family, and/or immigration from countries where universal screening is not performed.[4,8,21] SCD involves multiple organ systems, and its clinical manifestations vary greatly among genotypes (Table 124-1).[2,21,22]

TABLE 124-1

Clinical Features of Sickle Cell Trait and Common Types of Sickle Cell Disease

Type	Clinical Features
Sickle cell trait (SCT)	Rare painless hematuria; heavy exercise under extreme conditions can provoke gross hematuria and complications (normal Hb)
Sickle cell anemia (SCA- HbSS)	Pain episodes, microvascular disruption of organs (spleen, liver, bone marrow, kidney, brain, and lung), gallstones, priapism, leg ulcers; anemia (Hb 6-9 g/dL [60-90 g/L; 3.72-5.59 mmol/L])
Sickle cell hemoglobin C (HbSC)	Painless hematuria and rare aseptic necrosis of bone; pain episodes are less common and occur later in life; other complications are ocular disease and pregnancy-related problems; mild anemia (Hb 9-14g/dL [90-140 g/L; 5.59-8.69 mmol/L])
Sickle cell β^{+}-thalassemia (HbSβ^{+}-thal)	Rare pain; milder severity than HbSS because of the production of some HbA; Hb 9-12 g/dL (90-120 g/L; 5.59-7.45 mmol/L) with microcytosis
Sickle cell β^{0}-thalassemia (HbSβ^{0}-thal)	No HbA production; severity similar to SCA; Hb 7-9 g/dL (70-90 g/L; 4.34-5.59 mmol/L) with microcytosis

Data from References 1-4, and 22-24.

Persons with SCT are usually asymptomatic. However, under certain extreme situations where Hb oxygenation is altered, RBC sickling can occur in SCT. Sickling of RBCs in the renal medulla, an area with low-oxygen tension, can result in the inability to concentrate urine. Individuals with such impairment can be at risk of dehydration. Microscopic hematuria has been observed, and gross hematuria can occur after heavy exercise. Other reported complications associated with SCT are delayed hemorrhage after eye trauma, venous thromboembolism (VTE), particularly pulmonary embolism, and chronic kidney disease.[12,23] Individuals with SCT should be cautious when participating in exercise under extreme conditions, such as athletic or military training. The US Sudden Death in Athletes Registry reported that 0.9% of 2,462 deaths occurred in athletes with SCT. The events in those 23 athletes with SCT were sudden cardiovascular collapse followed by several minutes of gradually worsening symptoms including dyspnea, fatigue, and weakness during or after vigorous physical activity.[24] Preventive strategies such as gradual conditioning, adequate rest, and hydration are recommended to minimize the risk of sudden death in personnel undergoing athletic or military training.[12,24]

The cardinal features of SCD are hemolytic anemia and vasoocclusion. In individuals with HbSS, anemia usually develops from 4 to 6 months after birth. The delay is due to the presence of HbF in fetal RBCs. HbF production is gradually replaced by HbS, leading to the clinical manifestations of the disease, such as pain and swelling of the hands and feet, commonly referred to as *hand-and-foot syndrome* or *dactylitis* in infants.[4,5,10]

The common clinical signs and symptoms associated with HbSS include chronic anemia and pallor, fever, arthralgia, scleral icterus, abdominal pain, weakness, anorexia, fatigue, hematuria, and enlargement of the liver, spleen, and heart. Laboratory findings include low hemoglobin level around 6 to 9 g/dL (60-90 g/L; 3.72-5.59 mmol/L), elevated reticulocytes of 10% to 25%, elevated lactate dehydrogenase, and elevated platelet and white blood cell (WBC) counts. Mean corpuscular volume (MCV) is normal. The peripheral blood smear demonstrates sickled RBC forms.[4,22]

Individuals with HbSC disease usually present with less severe symptoms than HbSS. The condition is characterized primarily by mild anemia (Hb levels of 9-14 g/dL [90-140 g/L; 5.59-8.69 mmol/L] and reticulocytes of 5%-10%), persistence of splenomegaly into adult life, and excessive target cells in the peripheral blood smear. In individuals with heterozygous HbSβ-thalassemia syndrome, severity of disease depends on the thalassemia mutation involved.[4,22]

Many factors can influence disease severity and mortality in children and adults with SCD. Markers for disease severity in children include dactylitis before 1 year of age, average Hb less than 7 g/dL (70 g/L; 4.34 mmol/L) in the second year of life, and leukocytosis in the absence of infection. Reticulocytosis has been associated with increased death and morbidity in both children and adults.[25,26] Early acute chest syndrome (ACS) during the first 3 years of life is a predictor for recurrent episodes throughout childhood. Children with concomitant SCD and asthma have an increased risk of ACS and pain episodes and increased mortality. Factors associated with decreased survival in adults with SCD include frequency of sickle cell pain, elevated WBC, cerebrovascular events, renal failure, proteinuria, and pulmonary hypertension.[25-28] With improved survival for SCD, chronic manifestations of the disease contribute to the increased morbidity later in life. Additionally, genetic modifiers also affect the severity of SCD. For example, BCL11A is associated with the HbF concentration, and coincident α thalassemia reduces hemolysis.[1]

CLINICAL PRESENTATION: Sickle Cell Disease

General

- Most patients in the United States with SCD are diagnosed during newborn screening
- Patients usually have a history of anemia and vasoocclusive pain crisis

Symptoms

- Acute or chronic pain, painful swelling of hands and feet, weakness, anorexia, and fatigue

Signs

- Chronic anemia and pallor, scleral icterus, hematuria, and enlargement of spleen

Laboratory Tests

- Hemoglobin electrophoresis shows over 90% hemoglobin S without the presence of hemoglobin A for the HbSS or HbSβ^0 genotype, about 50% hemoglobin S and C respectively for the HbSC genotype. Low hemoglobin level, elevated reticulocytes, elevated lactate dehydrogenase, and elevated platelet and WBC count. The peripheral blood smear demonstrates sickled RBC forms.

COMPLICATIONS

Acute Complications

Fever and Infection

Functional asplenia and failure to make antibodies against encapsulated organisms contribute to the high risk of overwhelming sepsis in individuals with SCD. Penicillin prophylaxis and vaccination have significantly reduced the overall risk of *Streptococcus pneumonia* bacteremia, but nonvaccine serotypes of *Streptococcus pneumonia* have been reported.[4,6,13,29] Children with SCD remain at a greater risk of invasive pneumococcal infections when compared to those with other underlying diseases or healthy children.[29,30] Other encapsulated organisms are *Haemophilus influenzae, Neisseria meningitidis,* and *Salmonella*, with the latter known to cause osteomyelitis and pneumonia in SCD. *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* should be considered in older children with infiltrates on chest radiograph. Viral infections such as respiratory syncytial virus, influenza, and parvovirus B19, can result in severe morbidity.[4,31] In children with SCD admitted for bacteremia, coagulase-negative *Staphylococcus* was associated with central venous access; this infection should be considered for those with a permanent indwelling venous catheter. In adults, overt pneumococcal bacteremia is less common. Pathogens such as *Staphylococcus aureus* and gram-negative organisms are associated with immunosuppression, indwelling catheter, and bone and joint infections.[5,32]

All patients with SCD with fever greater than 38.5°C (101.3°F) must be evaluated for infection or sepsis and considered for empiric antibiotic therapy; those with temperature 39.5°C (103.1°F) and appearing ill should be hospitalized. Lumbar puncture may be needed, especially in young and toxic-appearing children.[3,4,22,32]

Children with SCD may experience an aplastic crisis, which is characterized by a decrease in the reticulocyte count, the rapid development of severe anemia, and hypoplastic bone marrow (Table 124-2). An aplastic crisis is most often associated with a viral infection, particularly parvovirus B19.[3,4]

TABLE 124-2

Acute Sickle Cell Complications

Acute chest syndrome[a]

Clinical features: Peak incidence between ages 2 and 4 years. Clinically resembles pneumonia. Viral causes are more common in children than adults. Hypoxia is associated with outcome.
Signs and symptoms: New radiographic pulmonary infiltrate with one or more of the following: cough, dyspnea, tachypnea, chest pain, fever, wheezing, and new-onset hypoxia (greater than 2% decrease from baseline).
Evaluation: Chest x-ray, CBC, Type and Screen, frequent O_2 monitoring, sputum culture, serology for respiratory organisms.
Acute splenic sequestration[b]
Clinical features: Acute exacerbation of anemia due to sequestration of large blood volume by the spleen. More commonly seen in patients with functioning spleens (eg, infants with HbSS and older children and rarely adults with HbSC disease); onset often is associated with viral or bacterial infections; recurrences are common and can be fatal.
Signs and symptoms: Sudden onset of fatigue, dyspnea, and distended abdomen; rapid decrease in Hb and Hct with elevated reticulocyte count, abdominal pain, splenomegaly, vomiting, hypotension, and shock.
Evaluation: Close monitoring of vital signs, spleen size, and oxygen saturation, CBC, reticulocyte count, type and screen and blood cultures.
Aplastic crisis[c]
Clinical features: Acute decrease in Hb with decreased reticulocyte count (usually <1%); transient suppression of RBC production in response to bacterial or viral infection, most common being parvovirus B19.
Signs and symptoms: Headache, fatigue, dyspnea, pallor, and tachycardia; can also present with fever, upper respiratory or gastrointestinal infection symptoms.
Evaluation: CBC, reticulocyte count, type and screen, cultures (blood, urine, and throat), evaluation of viral infection (eg, parvovirus titers).
Overt stroke[d]
Clinical features: Sudden onset but often proceeded by a transient ischemic attack. Commonly seen in patients with HbSS and $\text{HbS}\beta^0$-thal genotypes.
Signs and symptoms: Headache, paralysis or weakness, aphasia, visual disturbances, facial droop and convulsions.
Evaluation: Imaging, CBC, reticulocyte count, HbS quantification, type and screen, prothrombin time, activated partial thromboplastin time, and basic chemistry.
Vasoocclusive pain episodes[e]
Clinical features: Acute painful infarction without changes in Hb; almost all patients with SCA will have episodes of acute pain. Recurrent acute pain results in bone, joint, and organ damage and chronic pain. Vasoocclusive episodes most commonly involve the bones, liver, spleen, brain, lungs, and penis. Acute pain in long bones can be accompanied by signs of inflammation, making it difficult to differentiate from osteomyelitis. Abdominal involvement can resemble a surgical abdomen. Precipitating factors include infection, extreme weather conditions, swimming, excessive physical activity, dehydration, and stress.
Signs and symptoms: Deep throbbing pain; local tenderness, erythema, and swelling can be seen. Fever and leukocytosis are common. Dactylitis usually occurs in young infants. Jaundice and increased transaminases can be present if the liver is involved.
Evaluation: Frequent physical examination, CBC, reticulocyte count, and urinalysis. Based on symptomatology, the following may be needed: needle

aspiration to rule out osteomyelitis, abdominal studies (radiograph, computed tomography scan, etc.), liver function tests, bilirubin, blood culture, and chest radiograph.

Hct, hematocrit.

Neurologic

Neurologic abnormalities and cognitive deficits are well documented in patients with SCD. Vasoocclusive processes can lead to cerebrovascular occlusion that manifests as signs and symptoms of overt stroke (Table 124-2). The risk of stroke is highest for HbSS and lowest for HbSβ^+-thal. The incidence of cerebral infarction in HbSS is 11% by age 20 years and 24% by age 45 years with a recurrence rate as high as 70% in 3 years. The highest risk occurs during the first decades, in particular ages 2 to 5 years. The risk is lowest before age 2 secondary to the protective effect of HbF. Ischemic strokes occur in 54% of cerebrovascular accidents with the highest risk before age 10 years and after 30 years of age, whereas hemorrhagic strokes are more common when patients are in their twenties and are associated with poor outcome.[1,4,19,36,38]

In addition to neurologic examination, evaluation of acute events includes computed tomography scan and magnetic resonance imaging (MRI) of the brain. Asymptomatic or silent infarcts are detected by screening MRI. Transcranial Doppler ultrasound (TCD) is important in primary stroke prevention to identify children between 2 and 16 years with abnormal cerebral artery velocities, which are associated with a 40% risk of overt stroke in the subsequent 3 years. Other imaging studies are magnetic resonance angiogram to evaluate for cerebral vasculopathy in patients with persistently abnormal TCD, overt stroke or silent stroke; and magnetic resonance venography to evaluate for cerebral vein thrombosis. In addition, electroencephalography can be helpful in patients with a history of seizure.[4,5,22,36]

About 10% to 30% of individuals who have HbSS with no prior history of stroke have changes on MRI of the brain consistent with infarction or ischemia. Silent cerebral infarcts can be associated with an increased risk of stroke, decreased neurocognitive function, behavioral changes, and poor academic performance.[39] Neurological complications predispose aging adult patients to dementia. Finally, lower intelligence, visual-motor impairments, and neuropsychological dysfunction have been reported in patients not affected by acute or silent strokes and are associated with severity of anemia.[4,5,22,39]

Acute Chest Syndrome

ACS, defined as a new pulmonary infiltrate associated with fever and/or respiratory symptoms, is the second most common cause of hospitalization and a leading cause of death among individuals with SCD (Table 124-2).[1,33,34] The primary causes of ACS are pulmonary vascular occlusion and infection. Vascular occlusion can be caused by fat emboli released from bone marrow, VTE, or direct adhesion of RBCs to the pulmonary vasculature resulting in a vicious cycle of inflammation, hypoxia, and injury to the lung. The most common infectious pathogens causing ACS are *M. pneumonia,* respiratory syncytial virus, *C. pneumoniae*, *Staphylococcus aureus*, and *Streptococcus pneumoniae*.[1,4,33,34]

Risk factors for ACS and recurrence include young age, lower HbF, higher leukocytes, history of asthma or bronchial hyper-responsiveness, smoke exposure, and recent history of stroke (overt or silent) or vasoocclusion. Genotype and haplotype also influence risk. Patients with HbSS and HbSβ^0-thal have a higher risk than those with HbSC and HbSβ^+-thal and the risk is higher with African haplotypes than that of Saudi Arabia.[1,4,33,34]

ACS is more common in children but more severe in adults. Hypoxia is a predictor of severity and outcome. In severe cases, computed tomography scan, perfusion scintigraphy, transthoracic echocardiography, and bronchoscopy may be helpful to identify the etiology. Pulmonary changes often involve the lower lobes of the lungs and may cause pleural effusions. Bilateral infiltrates or multiple lobe involvement is associated with poor prognosis.[4,33,34] Pulmonary manifestations must be recognized early and managed aggressively as ACS can rapidly progress to pulmonary failure and death.[33,34]

Priapism

Stasis and sickling of RBCs within the sinusoids of the corpora cavernosa is the primary mechanism of priapism, a sustained painful erection of the penis. The pathophysiology of priapism at the molecular level includes abnormal NO signaling as the result of chronic NO depletion. Stuttering priapism is repeated intermittent attacks up to several hours before remission; ischemic priapism is a persistent painful erection greater than 4 hours and should be considered an emergency. Thirty percent to 45% of boys/men with SCD will present with at least one episode of priapism during their lifetime. The first episodes often occur during childhood. Impotence has been reported after repeated episodes and is directly related to the duration prior to treatment.[1,22,40]

Sickle Cell Pain

Acute episodes of pain are the most common reason for seeking treatment in SCD (Table 124-2). The usual cause of sickle cell pain is microvascular occlusion in the bone marrow. Although fever, infections, dehydration, hypoxia, acidosis, and sudden temperature alterations can precipitate pain, episodes are often unpredictable with no known triggers.[1,4,22] Dactylitis (hand-and-foot syndrome) is a subtype of sickle cell pain occurring in infancy and early childhood that usually does not result in permanent damage.[1,22] Each painful episode is associated with residual damage from inflammation that worsens with recurrence leading to more serious complications such as ACS.[37]

Sickle cell pain may be localized or migratory and is continuous and throbbing. The most common locations are the back, chest, and extremities but pain can occur in any location such as the abdomen or the head and lead to confusion with other acute complications such as stroke.[1,22] Risk factors associated with painful episodes include older age, iron overload, higher Hb, and lower HbF.[2,4,37]

Splenic Sequestration

Splenic sequestration is the sudden massive enlargement of the spleen resulting from the sequestration of sickled RBCs in the splenic parenchyma (Table 124-2). Hct and Hbhemoglobin concentrations fall dramatically with associated reticulocytosis and no evidence of marrow failure or accelerated hemolysis. The trapping of the sickled RBCs by the spleen leads to a decrease in circulating blood volume, which can result in hypotension and shock. The condition is most often seen in infants and children because their spleens are intact; it can cause sudden death in young children due to hypovolemia. Splenic enlargement may also be acutely painful due to rapid capsular expansion. Over time, repeated splenic infarctions lead to autosplenectomy and the spleen can no longer become engorged. Sequestration usually occurs between 1 and 4 years of age for children with HbSS and HbSβ^0-thal and not at older ages because autoinfarction usually is completed by then. For HbSC and HbSβ^+-thal, autoinfarction is delayed and sequestration can occur even during adulthood.[1,4,13,22,35]

Venous Thromboembolism

Patients with SCD are susceptible to VTE due to a hypercoagulable state, endothelial dysfunction, and impaired blood flow. In addition to inflammation and hemostatic abnormalities associated with the disease, other risk factors for thrombosis include central venous access, decreased mobility, and frequent hospitalizations. An increased risk of VTE, deep vein thrombosis, and pulmonary embolism has been reported to be independent of hospitalization frequency.[7,11,13,41] Prevalence rates of 7.4% by age 30 and 11.3% by age 40 were reported.[7] In addition, a recurrence rate of about 25% has been reported.[11] D-dimer testing cannot be used to detect deep vein thrombosis because elevated D-dimers are found in more than 90% of patients with SCD as a result of hemolysis.[13] Awareness of VTE is essential when evaluating patients presenting with ACS or vasoocclusive episodes. Management of VTE is based on the anticoagulation guidelines for the general public and the role of prophylaxis in patients with SCD is unclear.[7]

Chronic Complications

Pulmonary

Over 90% of children survive into adulthood, increasing the contribution of pulmonary manifestations to the morbidity and mortality of SCD. Physical exam and history should be performed to identify signs and symptoms of respiratory conditions such as asthma, restrictive lung disease, and chronic obstructive pulmonary disease. Pulmonary function testing is recommended in symptomatic patients but not as a routine screening tool. Lower predicted FEV1% was associated with earlier death in SCD.[2]

Pulmonary hypertension, defined as a resting mean pulmonary arterial pressure of 25 mm Hg or greater by right heart catheterization, is associated with increased morbidity and mortality in SCD. Symptoms of pulmonary hypertension include shortness of breath during normal activities, fatigue, syncope, and peripheral edema. A less invasive test, tricuspid regurgitant jet velocity by Doppler echocardiography, is frequently performed initially to estimate systolic pulmonary arterial pressure, but this test is not diagnostic of pulmonary hypertension. Serum N-terminal pro-brain natriuretic peptide (NT-pro-BNP) measurement is an alternative test that can be used to estimate the risk of pulmonary hypertension in patients with normal renal function when Doppler echocardiography is not an option. The American Thoracic Society recommends assessment of mortality risk with noninvasive (indirect) or invasive direct measurement to guide management of pulmonary hypertension (Table 124-3).[22,42,43]

TABLE 124-3

Risk Stratification and Management Recommendation for Pulmonary Hypertension

	Recommendations	Strength	Evidence Quality
Increased risk for mortality[a]	Hydroxyurea	Strong	Moderate
Increased risk for mortality, unresponsive or not candidates for hydroxyurea	Chronic transfusion therapy	Weak	Low
RHC-confirmed PH, venous thromboembolism, no risk factors for hemorrhage	Indefinite anticoagulant therapy	Weak	Low
Elevated TRV alone	No PAH therapy[b]	Strong	Moderate
Elevated NT-pro-BNP alone	No PAH therapy[b]	Strong	Moderate
RHC-confirmed marked elevation of pulmonary vascular resistance, normal pulmonary artery wedge pressure, presence of related symptoms	• A trial of prostacyclin agonist or endothelin receptor antagonist • Phosphodiesterase-5 inhibitor should not be used as first-line therapy	Weak Moderate	Very low Moderate

[a] Increased risk for mortality: (1) Tricuspid regurgitant jet velocity (TRV) greater than or equal to 2.5 m/s, (2) an N-terminal pro-brain natriuretic peptide (NT-pro-BNP) level greater than or equal to 16 pg/mL (ng/L; 1.9 pmol/L), or (3) right heart catheterization (RHC)-confirmed pulmonary hypertension (PH).

[b] PAH therapy: (1) prostacyclin agonist (epoprostenol, treprostinil, iloprost), (2) soluble guanylate cyclase stimulator (riociguat), (3) endothelin receptor antagonist (bosentan, macitentan, ambrisentan), and (4) phosphodiesterase-5 inhibitor (sildenafil, vardenafil, tadalafil).

Data from References [42], *and* [43].

Airway inflammation and hyper-responsiveness are common in SCD. Therefore, careful screening for respiratory symptoms in adults and children with

SCD is essential. Asthma and wheezing (with or without a diagnosis of asthma) in individuals with SCD have been associated with ACS and vasoocclusive pain episodes and increased mortality. Symptoms of asthma exacerbation can overlap with ACS making it difficult to differentiate the two.[1,4,13,27] For the management of asthma, the National Asthma Education and Prevention Program asthma management guideline should be utilized and inhaled corticosteroids are first line for persistent symptoms.[27]

Skeletal and Skin Diseases

Musculoskeletal complications from vasoocclusion are common in SCD and have a significant impact on quality of life. Osteonecrosis, particularly of the femoral or humeral heads, causes chronic pain, permanent damage, and disability.[11,44] Low bone mineral density can occur early with a prevalence of over 70% reported in adults with SCD. Osteopenia and osteoporosis associated with low bone formation have been reported in individuals with SCD.[4,45] Vitamin D deficiency is common in SCD, especially in children, and is associated with increased bone fragility and vasoocclusive pain episodes.[3-5] Children with SCD also have an increased incidence of osteomyelitis; the organism most often responsible is *Salmonella*.[4,45] Septic arthritis occurs in up to 5% of children but is rare in adults.[44] In addition to necrosis of joints, chronic leg ulcers, most commonly seen in the medial and lateral malleolus (ankles), can become a difficult and painful problem for adults. Ulcers are often seen after trauma or infection and are usually slow to heal.[5,22]

Ocular Manifestations

Ocular problems seen in patients with SCD include orbital and retinal manifestation. The incidence of proliferative sickle retinopathy and vitreous hemorrhage is up to 50%. Vasoocclusion in the eye can occur as early as 20 months of age. Clinically detectable retinal diseases usually occur during adolescence and early adulthood. Orbital involvement is uncommon but has a high potential for severe vision loss. Despite less systemic manifestations, individuals with HbSC develop serious retinal complications more often and earlier than those with HbSS. Lack of visual symptoms does not indicate the absence of ocular manifestations. Annual retinal examination starting at age 10 years is recommended for patients with SCD to prevent blindness from retinopathy and other complications.[22,46]

Hepatobiliary Diseases

Cholelithiasis is a common complication of SCD resulting from chronic hemolysis and increased bilirubin production, leading to biliary sludge and/or stone formation. The risk of gallstones increases with age: 12% for age 2 to 4 years, 43% by age 15 to 18 years, and 70% to 75% in adults. Cholecystitis, exemplified by pain in the right upper quadrant, can be confused with an acute sickle pain episode in the abdomen. Mild baseline hepatomegaly and elevation of liver function tests can occur in individuals with SCD. Cirrhosis occurred in 18% of young adults with SCD. Causes for the development of chronic hepatic disease include repeated occlusion in the liver, iron overload, and hepatitis.[22,47]

Cardiac Diseases

Cardiovascular complications associated with anemia, including cardiac enlargement and various murmurs, can occur in patients with SCD. Patients experience varying degrees of exertional dyspnea, tachycardia, and palpitation because of the decreased oxygen-carrying capacity of the blood. Left ventricular diastolic dysfunction has been reported in 18% of adults with SCD and is associated with increased mortality, especially in patients with pulmonary hypertension. Left ventricular stiffness and left ventricular hypertrophy have been reported, and can progress to diastolic dysfunction later in life. Acute myocardial infarction in adults with SCD may be under-recognized due to the high incidence of sickle cell acute chest pain.[1,10,48]

Renal Diseases

Renal dysfunction in SCD begins during infancy, as evidenced by glomerular hyperfiltration. Other manifestations include the inability to concentrate urine, hematuria, tubular acidosis, papillary necrosis, glomerulonephritis, microalbuminuria, and proteinuria. Enuresis, as a result of increased urine production, occurs in 42% of children ages 6 to 8 and 9% in young adults ages 18 to 20. Microalbuminuria, present in 42% of adults with the HbSS disease, is typically the first sign of chronic kidney disease, which has been associated with increased mortality.[6,7,22,49,50] In adults with SCD, cystatin C may better correlate with eGFR compared to serum creatinine.[7]

TREATMENT

Desired Outcomes

The goal of treatment is to reduce hospitalizations, complications, and mortality as well as improve quality of life. Management involves the use of general measures to meet the unique demands with the goal of preventing or treating complications of the disease. When an acute complication occurs, the type and severity of the episode determine the appropriate therapeutic plan.

With the availability of public health programs and comprehensive care, most children in developed countries survive through childhood and the burden of reducing mortality has shifted to focus on adults with SCD.[1,7,10] The life expectancy for individuals with SCD is lower than the general population by at least 20 years and a particularly vulnerable period appears to be during the transition to adult medical care.[4,7] Outcome evaluation for management of SCD should include assessment of health-related quality of life in both adults and children.

All patients with SCD should receive regularly scheduled comprehensive medical evaluations. Because of the complexity of the disease, an interprofessional team is needed to provide high-quality medical care, education, counseling, and psychosocial support. Appropriate comprehensive care can have a positive impact on both longevity and quality of life. This care includes the use of evidence-based treatment combining general symptomatic supportive care, preventative medical therapies, and specific disease modifying therapies aimed at altering hematologic capacity and function.

Routine Health Maintenance

SCD is a complex chronic disease involving multiple organs. In addition to the preventive care recommended for the general population, individuals with SCD also need health maintenance and screenings that focus on minimizing complications (Table 124-4).

TABLE 124-4

Health Maintenance

Invasive Pneumococcal Infection Prevention

1. Oral penicillin until age 5 for children with HbSS/Sβ°-thal
    a. Discontinue penicillin prophylaxis at age 5 unless have had splenectomy or invasive pneumococcal infection
2. Consider no penicillin prophylaxis for children with HbSC disease and HbSβ$^+$-thal unless they have had a splenectomy

Immunization

1. All individuals should receive immunization according to the Advisory Committee on Immunization Practices
2. Pneumococcal Vaccine
    a. All infants should receive complete series of PCV13
    b. All children should receive PPSV23 at age 2 years and second dose at age 5 years
    c. Children age 2-5 years with incomplete PCV13 vaccination
        Unvaccinated or less than three doses PCV13: Two doses of PCV13 with second dose 8 weeks apart
        Received three doses of PCV13 but none after 12-month of age: One dose of PCV 13
        Give two doses of PPSV23 after the PCV13 series completed. First dose at least 8 weeks after PCV13 and second dose at least 5 years later
    d. Children age 6-18 years not received PCV13 should receive one dose of PCV13.
    e. Children age 6-18 years not received PPSV23 should receive two doses of PPSV23. First dose at least 8 weeks after PCV13 and second dose at least 5 years later
    f. Adults age 19-64 years not previously received PCV13 or PPSV23:
        One dose PCV13
        Two doses PPSV23. First dose at least 8 weeks after PCV13 and second dose at least 5 years later
    g. Adults age 19-64 years previously received PPSV23
        One dose PCV13 at least 1 year after last PPSV23

One dose of PPSV23 at least 5 years after first dose and no sooner than 8 weeks after PCV13

3. Haemophilus Influenza (Hib) Vaccine
    a. Children age greater than 5 years who have not previously received Hib vaccine should receive one dose
4. Meningococcal Vaccine (indicated for persons have functional or anatomic asplenia)[a]
    a. Four-dose primary series to be administered with MenACWY-CRM (2, 4, 6, and 12 months)
    b. Booster dose to be administered with MenACWY-CRM or MenACWY-D
        Primary series completed prior to age 7: Booster dose 3 years after primary series and repeat every 5 years thereafter
        Primary series completed age 7 or older: Booster dose 5 years after primary series and repeat every 5 years thereafter
    c. Unvaccinated children 7-23 months: Two doses of MenACWY-CRM with second dose at least 12 weeks after the first dose AND after first birthday
    d. Unvaccinated children age 2 years or older and adults: Two doses of MenACWY-CRM or MenACWY-D 8-12 weeks apart
        MenACWY-D to be given at least 4 weeks after completion of all PCV13 doses
    e. Adults previously vaccinated should receive MenACWY-CRM or MenACWY-D every 5 years
    f. Serogroup B Meningococcal (MenB): Age 10 or older
        MenB-FHbp (Trumenba®): Three-dose series (at 0, 1-2, and 6 months); or two-dose series (at 0 and 6 months)
        MenB-4C (Bexsero®): Two-dose series at least 1 month apart
5. Influenza vaccine annually for age 6 months and older

Renal

1. Screen for proteinuria by age 10 and annually if negative
2. Initiate ACE inhibitor for adults with microalbuminuria or proteinuria without apparent cause

Pulmonary Hypertension (PH)

1. Noninvasive tests (Doppler echocardiography or alternatively, serum NT-pro-BNP measurement) can be used to assess mortality risk
2. Echocardiogram to screen for PH and associated cardiac problems by age 8 for those with frequent cardiorespiratory symptoms
3. The optimal frequency for Doppler echocardiography is unknown but every 1-3 years seems to be reasonable
4. Children with evidence of PH by echocardiogram should be further evaluated: Pulmonary function test, polysomnography, oxygenation assessment, and thromboembolic disease
5. Cardiac catheterization should be performed before initiation of PAH-specific therapy

Ophthalmological Evaluation

1. Dilated eye examination begins at age 10 and rescreen at 1-2 year intervals

Stroke Prevention

1. Children with SCA: Transcranial Doppler (TCD) annually beginning at age 2 until at least age 16
2. Chronic transfusion therapy for stroke prevention in children with elevated (>200 cm/s) TCD results

[a] Brand name for meningococcal vaccine: MenACWY-CRM (Menveo®), and MenACWY-D (Menactra®)

Data from References [22,32,35,42], *and* [51-54].

PCV13, 13-valent conjugate pneumococcal vaccine; PPSV23, 23-valent pneumococcal polysaccharide vaccine; ACE Inhibitor, angiotensin converting enzyme inhibitor; PAH, pulmonary artery hypertension; PH, pulmonary hypertension.

Growth and development in children with SCD should be monitored as delayed growth and sexual maturation are common.[4,10,39] Depression, anxiety, and other behavior issues are more common in children and adults with SCD than in the general population and have a significant impact on quality of life. Psychosocial supports are essential elements of care for individuals with SCD as well as their caretakers.[9,55] Pregnancy introduces an increased risk for the mother with SCD and for the fetus. Reproductive counseling and education should be incorporated into the care of individuals with SCD.[22,56]

Immunizations

Administration of routine immunizations is crucial preventive care in managing SCD. Children 6 months and older and adults with SCD should receive influenza vaccine annually. The COVID-19 vaccine should also be recommended to individuals with SCD. The most updated immunization and catch-up schedules are provided by the Centers for Disease Control and Prevention (http://www.cdc.gov/vaccines/schedules).

Impaired splenic function increases susceptibility to infection by encapsulated organisms, particularly *Streptococcus pneumoniae*. Prior to the routine use of penicillin prophylaxis and the development of pneumococcal vaccines, invasive pneumococcal disease was 20- to 100-fold more common in children with SCD than in healthy children. Reduced mortality has been associated with the introduction of pneumococcal vaccines.[1,4]

Two different pneumococcal vaccines are available. The 13-valent pneumococcal conjugate vaccine (PCV13) induces good antibody responses in infants and children less than 2 years of age. Immunization with the PCV13 is recommended for all children, regardless of SCD status, younger than 24 months of age. Infants should receive the first dose after 6 weeks of age. Two additional doses should be given at 2-month intervals, followed by a fourth dose at age 12 to 15 months. The 23-valent pneumococcal polysaccharide vaccine (PPSV23) is recommended for all children with functional or acquired asplenia but must be given after 2 years of age because of poor antibody response. To cover different serotypes, PPSV23 should be given starting at 2 years of age, and be administered 2 months after the last dose of the PCV13. A booster dose of PPSV23 is recommended 5 years after the first dose. Both pneumococcal vaccines are recommended for adults with certain medical conditions, including SCD (Table 124-4).[51]

The risk of meningococcal disease is also higher in SCD and vaccination is recommended for individuals with functional or acquired asplenia. Two types of meningococcal vaccines are available: (1) quadrivalent (serogroups A, C, Y, and W-135) meningococcal conjugate vaccines (MenACWY-CRM and MenACWY-D) and (2) meningococcal group B vaccine (MenB-FHbp and Menb-4C). Infants with functional asplenia should receive four-dose series with MenACWY-CRM at 2, 4, 6, and 12 months. Children over 2 years and adults with functional or acquired asplenia should receive a primary immunization series with two doses of the quadrivalent vaccine given 8 weeks apart. MenACWY-D should be given at age 2 years or older and at least 4 weeks after completion of all PCV13. A booster is recommended every 5 years for individuals with SCD.[22,52,54] Group B meningococcal vaccination is given to children with functional asplenia 10 years of age or older as a two-dose (MenB-FHbp or Menb-4C) or three-dose (MenB-FHbp) immunization series and these two vaccines are not interchangeable (Table 124-4).[52,54]

Pharmacologic Therapy

Penicillin

④ Penicillin prophylaxis until at least 5 years of age is recommended in children with SCD HbSS or HbSβ^0-thal, even if they have received PCV13 or PPSV23 immunization, as prophylaxis against invasive pneumococcal infections. An effective regimen that reduces the risk of pneumococcal infections by 84% is penicillin V potassium at a dosage of 125 mg orally twice daily until the age of 3 years, followed by 250 mg twice daily until the age of 5 years. Individuals who are allergic to penicillin can be given erythromycin 20 mg/kg/day. Penicillin prophylaxis is not routinely given in older children, based on a study demonstrating no benefit over placebo beyond the age of 5 years. However, continuation of oral pneumococcal prophylaxis should be considered on a case-by-case basis and is recommended for anyone with a history of invasive pneumococcal infection or surgical splenectomy.[22,32]

Hydroxyurea

HbF reduces polymer formation of HbS due to its high oxygen affinity and its inability to polymerize with HbS. Higher HbF levels are associated with decreased RBC sickling and RBC adhesion and observational studies show a relationship between higher HbF concentration and lower severity of SCD. Individuals with SCD and low HbF levels experience more frequent pain and higher mortality. HbF levels of 20% or greater are associated with a lower risk of acute sickle cell complications. Based on these observations, HbF induction has become a treatment modality for patients with SCD.

Hydroxyurea, a chemotherapeutic agent, stimulates HbF production and increases the number of HbF-containing reticulocytes and intracellular HbF. The drug inhibits DNA synthesis by blocking the conversion of ribonucleoside to deoxyribonucleotides. The exact mechanism of HbF production is unknown, but its myelosuppressive effect stimulates stress erythropoiesis, triggers rapid erythroid regeneration, and shifts erythrocyte Hb production to HbF. In addition, hydroxyurea increases NO levels, reduces neutrophils and monocytes, has antioxidant properties, alters the RBC membrane, increases RBC deformability by increasing intracellular water content, and decreases RBC adhesion to the endothelium.

Hydroxyurea is FDA-approved for patients 2 years of age and older with recurrent moderate-to-severe painful crises to reduce the frequency of painful crises and the need for blood transfusions. The Multicenter Study of Hydroxyurea in Sickle Cell Anemia (MSH Trial) was the first double-blind, placebo-controlled randomized controlled trial of hydroxyurea in adults with SCD. In that study, hydroxyurea significantly reduced the frequency of painful episodes, risk of ACS, need for blood transfusions, and number of hospitalizations in adults with SCD. A follow-up study showed a 40% reduction in mortality with hydroxyurea over a 9-year period and this trend continued when the original 299 patients from the MSH study were followed for 17.5 years.[10,26,57,58]

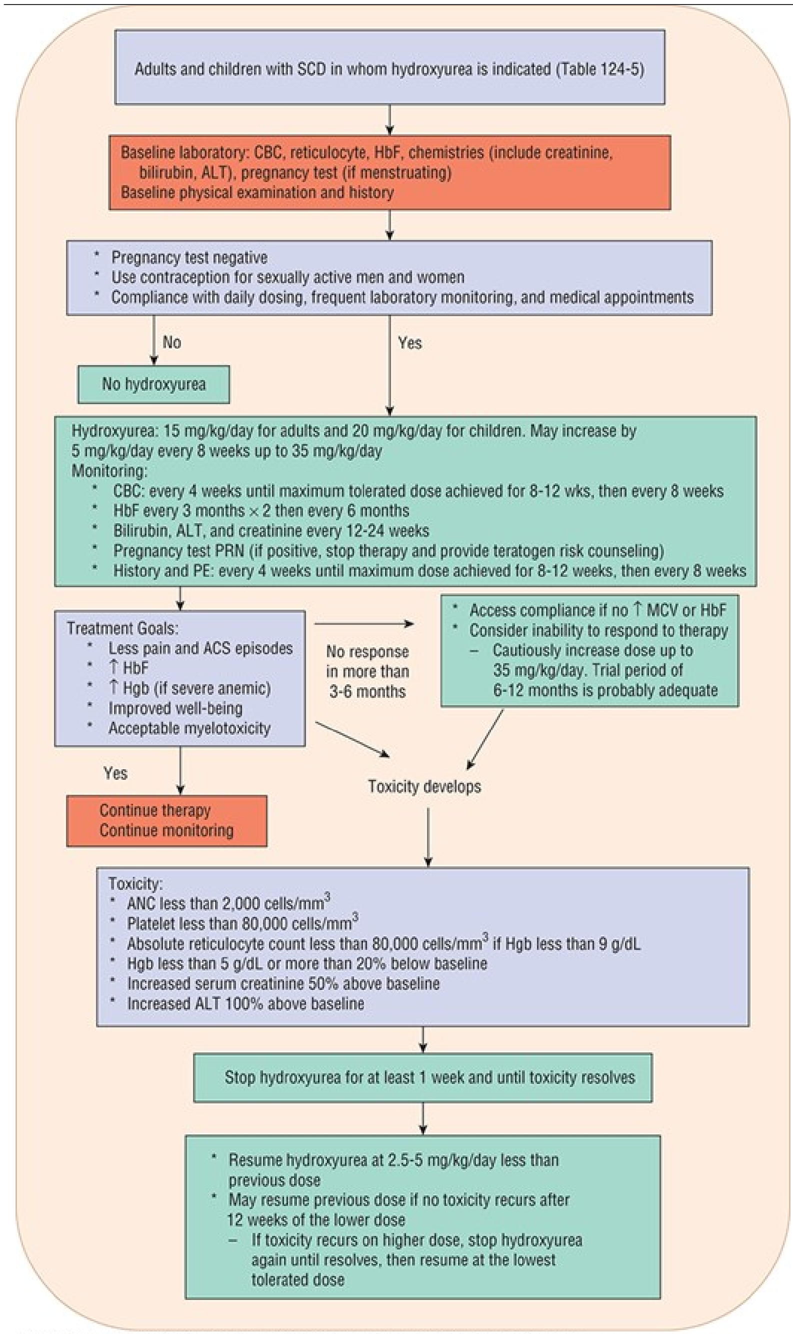
Studies in pediatric patients reported similar results to the MSH Trial with no adverse effects on growth and development. Some patients treated with hydroxyurea had possible recovery or preservation of splenic and brain function, including cognitive performance. The Transcranial Doppler with Transfusions Converting to Hydroxyurea study (TWiTCH) closed early after interim analysis showed that hydroxyurea was not inferior to chronic blood transfusions to prevent primary stroke. However, the Stroke with Transfusions Changing to Hydroxyurea (SWiTCH) trial also closed early when the interim analysis showed that hydroxyurea was inferior to chronic transfusions to prevent recurrent stroke. Therefore, chronic transfusion with iron chelation to treat transfusion-related iron overload is the preferred therapy to prevent stroke.[10,26,57,58] Initiating hydroxyurea early, prior to the development of complications may be beneficial. The Pediatric Hydroxyurea Phase III Clinical Trial (BABY HUG) randomized young children ages 9 to 18 months to hydroxyurea or placebo. Although investigators found no significant difference in the primary endpoints (splenic and renal function), children treated with hydroxyurea had fewer episodes of pain and dactylitis with no significant toxicities.[6,57,59] Hydroxyurea reduced the risk of painful events, ACS, renal enlargement, hospitalizations, and transfusions. In addition, improved urine concentration ability as demonstrated by higher urine osmolality was reported.[57,58] In a retrospective study of hydroxyurea therapy in children aged 3 to 18 years with SCD, a significant reduction in mortality, fewer hospitalizations and emergency visits, and shorter hospital stays were reported.[60]

The most common adverse drug reaction of hydroxyurea is bone marrow suppression, resulting in neutropenia, thrombocytopenia, anemia, and decreased reticulocyte count. These hematologic adverse drug reactions usually recover within 2 weeks of therapy discontinuation. Other adverse drug reactions include dry skin and hyperpigmentation of skin or nails.[4,22,57,59] Long-term adverse effects of hydroxyurea therapy in patients with SCD are not fully known, although no serious adverse effects were reported in the long-term (17.5 years) follow-up study of the MSH trial. There is no delays in growth or puberty, increased risk of infections, or genotoxicity for children.[61] Myelodysplasia, acute leukemia, and chronic opportunistic infection associated with T-lymphocyte abnormalities have been reported in other patient populations treated with higher doses of hydroxyurea. Reproductive toxicity is also a concern. High-dose hydroxyurea is teratogenic in animals, but normal pregnancies have been reported in women with SCD who received hydroxyurea during pregnancy.[57]

Although hydroxyurea was only FDA-approved for patients age 2 years and older with SCD in 2017, the agent has been used in pediatric patients for years.[1,3,4,22] Clinical indications for hydroxyurea include frequent painful episodes, severe symptomatic anemia, a history of ACS, or other severe vasoocclusive complications (Table 124-5). The starting dose for adults is 15 mg/kg/day rounded to the nearest 500 mg as a single daily dose. A lower dose of 5 to 10 mg/kg/day is used for patients with chronic kidney disease. The recommended initial dose for children is 20 mg/kg. Dosage can be increased by 5 mg/kg up to a maximum of 35 mg/kg in 8-week intervals if the patient does not demonstrate adverse drug reactions and blood counts are stable (Fig. 124-6). Hydroxyurea dosage should be individualized based on response and toxicity. In general, 3 to 6 months of therapy are required before improvement is observed. Medication adherence can be an issue. Since the MCV generally increases as the level of HbF increases, monitoring MCV is an inexpensive and convenient method to monitor response and adherence.[1,3,4,22,57]

FIGURE 124-6

Hydroxyurea use in sickle cell disease. Blood test results expressed in SI units that are consistent with toxicity are <2 × 10^9/L for ANC; <80 × 10^9/L for platelets; <80 × 10^9/L for absolute reticulocyte count if Hb <90 g/L (5.59 mmol/L); and Hb <50 g/L (3.10 mmol/L). (ALT, alanine aminotransferase; ANC, absolute neutrophil count; PE, physical examination; PRN, as needed.) (*Data from References [1, 3, 4, and 22].*)



Adults and children with SCD in whom hydroxyurea is indicated (Table 124-5)

Baseline laboratory: CBC, reticulocyte, HbF, chemistries (include creatinine, bilirubin, ALT), pregnancy test (if menstruating)
Baseline physical examination and history

- Pregnancy test negative
- Use contraception for sexually active men and women
- Compliance with daily dosing, frequent laboratory monitoring, and medical appointments

No hydroxyurea

Hydroxyurea: 15 mg/kg/day for adults and 20 mg/kg/day for children. May increase by 5 mg/kg/day every 8 weeks up to 35 mg/kg/day
Monitoring:

- CBC: every 4 weeks until maximum tolerated dose achieved for 8-12 wks, then every 8 weeks
- HbF every 3 months × 2 then every 6 months
- Bilirubin, ALT, and creatinine every 12-24 weeks
- Pregnancy test PRN (if positive, stop therapy and provide teratogen risk counseling)
- History and PE: every 4 weeks until maximum dose achieved for 8-12 weeks, then every 8 weeks

Treatment Goals:

- Less pain and ACS episodes
- ↑ HbF
- ↑ Hgb (if severe anemic)
- Improved well-being
- Acceptable myelotoxicity

No response in more than 3-6 months

- Access compliance if no ↑ MCV or HbF
- Consider inability to respond to therapy
  - Cautiously increase dose up to 35 mg/kg/day. Trial period of 6-12 months is probably adequate

Continue therapy
Continue monitoring

Toxicity develops

Toxicity:

- ANC less than 2,000 cells/mm^3
- Platelet less than 80,000 cells/mm^3
- Absolute reticulocyte count less than 80,000 cells/mm^3 if Hgb less than 9 g/dL
- Hgb less than 5 g/dL or more than 20% below baseline
- Increased serum creatinine 50% above baseline
- Increased ALT 100% above baseline

Stop hydroxyurea for at least 1 week and until toxicity resolves

- Resume hydroxyurea at 2.5-5 mg/kg/day less than previous dose
- May resume previous dose if no toxicity recurs after 12 weeks of the lower dose
  - If toxicity recurs on higher dose, stop hydroxyurea again until resolves, then resume at the lowest tolerated dose

TABLE 124-5

Recommendations on Hydroxyurea Therapy

	Recommendation	Strength	Evidence Quality
Adults with HbSS or HbSβ^0-thalassemia			
- Three or more sickle cell–associated moderate-to-severe pain crises per year	Treat with hydroxyurea	Strong	High
- Sickle cell–associated pain that interferes with daily activities and quality of life		Strong	Moderate
- History of severe and/or recurrent ACS		Strong	Moderate
- Severe symptomatic chronic anemia that interferes with daily activities or quality of life		Strong	Moderate
Infants 9 months of age and older, children, and adolescents with HbSS or HbSβ^0-thalassemia regardless of clinical severity	Offer hydroxyurea	Strong	High (age 9-42 months); Moderate (>42 months)
Sickle nephropathy with persisting proteinuria despite therapy	Consider hydroxyurea	Weak	Low
Chronic hypoxia	Treat with hydroxyurea	Strong	Low
HbSC or HbSβ^+-thalassemia with recurrent sickle cell–associated pain that interferes with daily activities or quality of life	Consider hydroxyurea	Moderate	Low
History of stroke and unable to implement chronic transfusion	Initiate hydroxyurea	Moderate	Low

Data from References [57, and 58].

⑤ Patients receiving hydroxyurea should be closely monitored for toxicity. Blood counts should be checked every 2 weeks during dose titration and every 4 to 8 weeks thereafter. Treatment should be interrupted if hematologic indices fall below the following values: absolute neutrophil count, 2,000 cells/mm^3 (2×10^9/L); platelet count, 80,000 cells/mm^3 (80×10^9/L); hemoglobin, 5 g/dL (50 g/L; 3.1 mmol/L); or reticulocytes, 80,000 cells/mm^3 (80×10^9/L) if the Hb concentration is less than 9 g/dL (90 g/L; 5.59 mmol/L). Other laboratory abnormalities warranting temporary discontinuation of therapy are a 50% increase in serum creatinine and a 100% increase in transaminases. After recovery has occurred, treatment should be resumed at a dose that is 5 mg/kg/day lower than the dose associated with toxicity. If no toxicity occurs after 12 weeks with the lower dose, the dose can be increased by 2.5 to 5 mg/kg/day. If the increased dose produces hematologic toxicity, the patient should be maintained at the last tolerated dose with no further escalation except for normal growth or weight gain.[22,57,58]

L-Glutamine

Sickled RBCs are susceptible to oxidative damage leading to hemolysis and vasoocclusion. Glutamine, an essential amino acid, is a precursor for nicotinamide adenine dinucleotide (NAD^+) synthesis. There is an increased uptake of glutamine by sickle RBCs, mainly to produce NAD^+. Children with SCD have lower glutamine levels; an increase of NAD^+ can potentially restore the redox balance in oxidative stressed cells.

In a phase III double-blind, placebo-controlled trial, L-glutamine significantly reduced the median number of pain episodes and the number of hospitalizations over the study period of 48 weeks. L-glutamine was well tolerated overall but nausea, noncardiac chest pain, fatigue, and musculoskeletal pain were more commonly reported in the L-glutamine group.[62]

L-glutamine was FDA-approved in July 2017, becoming the first product approved for pediatric patients with SCD and the first new treatment for adults in almost 20 years. It is indicated for patients with SCD age 5 and older to reduce the acute complications of SCD. The product is available in 5-g packets and should be mixed with 8 ounces of liquid (~240 mL) or 4 to 6 ounces (~110-170 g) of food. The recommended dose is based on weight: 5 g twice a day for less than 30 kg; 10 g twice a day for 30 to 65 kg and 15 g twice a day for greater than 65 kg. The most common gastrointestinal adverse drug reactions are constipation, abdominal pain, and nausea.[63]

Crizanlizumab

Adherence of erythrocytes and leukocytes to the endothelium causes vascular obstruction in SCD and increased severity of the disease. The expression of adhesion molecules, including P-selectin, on the surface of endothelial cells and platelets, contributes to this process. Blockage of P-selectin reduces the adhesion of sickle erythrocytes and leukocytes, and improves microvascular blood flow. Thus, P-selectin plays an important role in vasoocclusion and microcirculatory abnormalities in SCD.[8,9]

Crizanlizumab is a monoclonal antibody against P-selectin. In a phase II double-blind, randomized, placebo-controlled trial (the SUSTAIN trial), high-dose crizanlizumab (5 mg/kg) significantly reduced the annual rate of vasoocclusive crises from 2.98 per year in the placebo group to 1.63 per year (45% reduction) and increased the median time to the first vasoocclusive crisis. The risk of serious adverse drug reactions was similar between crizanlizumab and placebo groups, with arthralgia, diarrhea, pruritus, vomiting, and chest pain more common in the crizanlizumab group.[10]

Crizanlizumab was granted FDA approval in November 2019; it is indicated for patients ≥16 years old with SCD. It is available as an intravenous (IV) solution (100 mg/10 mL). The dosing regimen is 5 mg/kg once every 2 weeks for the first two doses, followed by 5 mg/kg once every 4 weeks.

Voxelotor

The sickling and unsickling process of erythrocytes due to HbS polymerization damages the cell membrane and results in hemolysis. It contributes to SCD-related complications, including anemia, pulmonary hypertension, leg ulcers, priapism, and chronic kidney disease, and can be mitigated by inhibiting HbS polymerization.[11]

In a phase III double-blind, randomized, placebo-controlled trial (the HOPE trial), 274 patients with SCD were randomly assigned to the placebo, the 900 mg or the 1,500 mg voxelotor group. The percentage of patients with an Hb increase of more than 1 g/dL (10 g/L; 0.62 mmol/L) after 24-week treatment was significantly higher in the 1,500 mg voxelotor group than in the placebo group. The voxelotor group also experienced improvement in the hemolytic markers. The risk of adverse drug reactions was comparable in all three groups, with headache and diarrhea reported in ≥20% of the 1,500 mg voxelotor group.[12] Similar results were observed after 72-week treatment.[13]

In November 2019, FDA approved voxelotor for the treatment of SCD in patients ≥12 years of age. It is available in oral tablet of 500 mg, and the recommended dose is 1,500 mg taken once daily, with a dose adjustment to 1,000 mg once daily in severe hepatic impairment (Child Pugh class C). As a CYP3A4 substrate, concomitant use of voxelotor with strong CYP3A4 inducers or inhibitors should be avoided, or dose adjusted if not avoidable.

Chronic Transfusion Therapy

RBC transfusions play an important role in the management of SCD. In acute illness, transfusions can be life-saving. Chronic transfusion programs can prevent complications of SCD. The primary indication for chronic transfusion is primary and secondary stroke prevention and amelioration of organ damage.[4,64] Blood transfusions can be administered as a simple transfusion, a manual exchange or an automated exchange called erythrocytapheresis. Exchange transfusion frequently requires permanent venous access and is associated with higher cost but has the advantage of increasing normal (donor) HbA, limiting volume, minimizing hyperviscosity, and limiting transfusional iron overload.[22]

⑥ Chronic transfusions should be considered in children with SCD and adults with previous stroke or children with abnormal TCD measurements.[22] Prophylactic transfusions reduced the incidence of first stroke from 16% to 2% over a 2-year period in children 2 to 16 years of age who were at an increased risk for stroke based on abnormal annual TCD screening.[64] In children with an overt stroke, chronic transfusions reduced stroke recurrence from about 50% to about 10% over 3 years. Chronic transfusions may also be useful in patients with severe or recurrent ACS, debilitating pain, chronic organ failure, intractable leg ulcers, severe chronic anemia with cardiac failure, and complicated pregnancies, although support for the efficacy of chronic transfusion in these situations is limited.[65]

The goal of transfusions is to achieve and maintain an HbS concentration of less than 30% of total hemoglobin in the primary and secondary prevention of neurologic complications. Transfusions are usually given every 3 to 4 weeks, but the frequency of transfusion is adjusted to maintain the desired HbS levels. The risk of recurrent stroke decreases after 2 years of transfusion therapy and, in the absence of recurrent stroke, many clinicians will liberalize the HbS goal to less than 50%.[4,64] The optimal duration of primary prophylactic transfusion therapy in children with abnormal TCD is not clear. Based on the results of the TWiTCH trial, some patients can safely transition to hydroxyurea therapy after normalization of TCD and no evidence of cerebral vasculopathy with at least a 6-month overlap in transfusions and hydroxyurea therapy. Discontinuation of transfusions has been associated with a 50% stroke recurrence rate within 12 months in children with a previous stroke and abnormal blood flow velocity on TCD. For secondary stroke prevention, transfusions should be continued indefinitely.[4,57,64] Hydroxyurea could be started prior to discontinuation of transfusion for secondary stroke prevention with at least a 6-month overlap with transfusions. However, the phase III trial of switching hydroxyurea for transfusion in secondary stroke prevention, the SWiTCH trial, was closed early due to an increased risk of recurrent strokes in the hydroxyurea arm when compared to the transfusions arm.[38] The National Institutes of Health recommends hydroxyurea for prevention of recurrent stroke only if implementation of a transfusion program is not possible.[22]

Although the benefits of transfusion therapy are clear in some clinical situations, its role in other situations such as priapism or an acute pain episode remains controversial.[22] The risks of transfusion therapy must be weighed against possible benefits. The risks associated with transfusion therapy include alloimmunization (sensitization to the blood received), hyperviscosity, transfusion-transmitted viral infections, volume overload, iron overload, and nonhemolytic transfusion reactions. The use of leukocyte-reduced RBC transfusions in chronically transfused patients can reduce the risk of nonhemolytic transfusion reactions.[4,64,65] All patients should be immunized with hepatitis A and B vaccines. Other viruses that can be transmitted through blood products are parvovirus B19, hepatitis C, cytomegalovirus, and HIV.[32,64]

Alloimmunization or alloantibody formation results from antigen differences on the red cell surface between the primarily Caucasian donor pool and recipients with SCD and can cause delayed hemolytic transfusion reactions (DHTRs). Alloimmunization occurs in 19% to 37% of SCD patients who receive RBC transfusions and can make it difficult to find cross-matched blood. To prevent alloimmunization, patients receiving chronic transfusions should receive the best cross-matched blood including extended typing of other RBC antigens especially C, E, and Kell or full RBC phenotyping.[22,64,65]

The development of alloimmunization can be life threatening for individuals with SCD. DHTRs usually occur within 7 to 10 days after transfusion of blood to which the recipient is immunized, but it can occur as early as 2 days or as late as 20 days after transfusion. During a DHTR, patients develop worsening pain, especially abdominal pain, severe anemia due to hemolysis of the transfused unit and reticulocytopenia, further aggravating the anemia. Subsequent transfusions can further worsen the clinical situation because of the presence of multiple antibodies making cross-matching difficult. Life-threatening events can be treated with steroids and intravenous immunoglobulin. Recombinant erythropoietin has been used in patients with reticulocytopenia.[22,64,65] Recovery, as evidenced by reticulocytosis with a gradual increase in the Hb level, may occur only after further transfusions are withheld. Although some patients tolerate further transfusions after recovery, especially if the donor unit is negative for the offending alloantibody, others cannot avoid recurrent transfusions and may experience another hemolytic transfusion reaction. Rituximab has been used to prevent recurrent DHTR. It is generally preferable to prevent the development of DHTR by performing RBC phenotyping and, at a minimum, transfusing individuals with blood that is C, E, and Kell negative.[4,22,65]

Transfusional iron overload is an important complication of RBC transfusions and patients should be instructed to not take iron supplements.[64,65] Abnormal liver biopsy results showing mild-to-moderate inflammation, fibrosis, or cirrhosis have been reported. Iron overload assessments, including serum ferritin and liver function tests, should be performed semiannually. Iron overload can be confirmed by liver biopsy or less invasively by MRI.[22,65] Three chelating agents are available. Deferoxamine has been used as a chelating agent for decades but must be administered by subcutaneous or intravenous infusion. The oral chelation agents, deferasirox and deferiprone, are as effective as deferoxamine with acceptable safety profiles in long-term studies up to 5 years.[66-68] Deferasirox is available in two forms. Exjade® is a dissolving tablet given once daily on an empty stomach starting at 20 mg/kg/day. Jadenu® is given as a film-coated tablet or sprinkle granule once daily on an empty stomach or with a light meal starting at a lower dose of 14 mg/kg/day. The common adverse drug reactions for deferasirox are transient skin rash and gastrointestinal symptoms such as nausea, vomiting, diarrhea, and abdominal pain. However, some patients may prefer film-coated tablets as it is more palatable and can be taken with food. Deferiprone has good oral bioavailability but a short half-life. The usual starting dose for deferiprone is 75 mg/kg/day, given in three divided doses. Similar to deferasirox, the common adverse drug reactions for deferiprone are rashes and gastrointestinal symptoms but the most concerning adverse drug reactions are neutropenia and agranulocytosis. For patients who require more aggressive management, deferoxamine in combination with either oral agent has been reported.[66-69]

Allogeneic Hematopoietic Stem Cell Transplantation

Allogeneic HSCT is a curative therapy for patients with SCD. The overall and disease-free survival rate for children and young adults with human leukocyte antigen (HLA)-matched sibling donors has been reported at 95% to 98% and 87% to 92%, respectively.[70,71] The reported incidences of acute and chronic graft-versus-host disease (GVHD) ranged from 5% to 17% and 0% to 3%, respectively. Other complications included seizures, marrow rejection, and sepsis. Improved growth, stabilization or improvement of CNS abnormalities, and recovery of splenic dysfunction were observed in posttransplant patients with SCD, but gonadal failure and delayed sexual development in girls requiring hormonal replacement have been reported.[72]

The optimal candidates for matched sibling donor transplant are SCD patients with severe disease (HbSS and HbSβ^0) prior to the onset of SCD symptoms, but the procedure should also be considered in patients with a history of stroke, elevated TCD velocity, recurrent ACS, recurrent pain, red cell alloimmunization on chronic transfusion protocol, pulmonary hypertension, and sickle nephropathy.[73,74] Unfortunately, many children who are eligible for HSCT do not have an HLA-matched sibling donor and unrelated HLA-matched transplants are associated with higher transplant-related mortality. However, matched unrelated allogeneic HSCT is considered for SCD patients who are younger than 16 years of age and have severe complications from SCD. Because allogeneic HSCT performed in young children before organ damage and alloimmunization occur is associated with increased success, counseling and screening for HLA-matched sibling donors during the first year of life is recommended. The risks associated with allogeneic HSCT must be carefully considered, as the transplant-related mortality rate is about 5% to 10%, and graft rejection is about 10%. Other risks associated with allogeneic HSCT include secondary malignancies. Neurologic events, such as intracranial hemorrhage and seizures during transplant, were seen more frequently in patients with a history of stroke.[73,74] Tacrolimus and cyclosporine should be used with caution and the blood pressure aggressively controlled due to the increased risk of posterior reversible encephalopathy syndrome, estimated to be 22%, with calcineurin inhibitors in SCD patients undergoing allogeneic HSCT.[75]

Umbilical cord blood is another potential donor source of hematopoietic stem cells with some advantages over marrow donors, including a lower incidence of severe GVHD and a larger donor pool from which to select donors, but such advantages are offset by longer time to engraftment and a higher rate of graft rejection.[72-74] Several protocols are under investigation with haploidentical donors, such as parents, for patients with recurrent stroke on chronic transfusions or severe SCD symptoms with no HLA-matched sibling donors. Recent studies with haploidentical donors have reported stable engraftment and low rates of acute and chronic GVHD, leading to similar outcomes compared to HSCT with HLA-matched donors.[76]

HSCT with myeloablative conditioning has traditionally been limited to children and young adults with SCD due to an increased risk of GVHD or transplant-related mortality with older age.[77] HSCT with HLA-matched donors and nonmyeloablative conditioning regimens resulted in mixed donor-recipient chimerism, reversal of acute SCD complications, and low rates of transplant-related toxicity or GVHD.[70-72,74] Conditioning with alemtuzumab, total body irradiation, and post-transplant sirolimus in adults with SCD up to the age of 65 years old resulted in stable engraftment in 87% of recipients with no observed chronic GVHD.[78]

TREATMENT OF COMPLICATIONS

Parents and older children should be educated on the signs and symptoms of complications and conditions that require urgent evaluation. During acute illness, patients should be evaluated promptly because deterioration can occur rapidly. Fluid balance should be maintained as either dehydration or fluid overload can worsen complications associated with SCD. Oxygen saturation by pulse oximetry should be maintained at least 92% or at baseline. New or increasing supplemental oxygen requirements should be investigated.

Acute Sickle Cell Pain

Hydration and analgesia are the mainstays of treatment for vasoocclusive (painful) episodes (Table 124-6). Patients with mild pain crises can be treated as outpatients with rest, increased fluid intake, warm compresses, and oral analgesics. Hospitalization is necessary for moderate-to-severe pain or when oral analgesics fail to relieve pain. A pain episode may be precipitated by several risk factors including infection. In the setting of pain and fever, an infectious etiology should be considered and appropriate empiric therapy should be initiated. In patients with severe symptomatic anemia, transfusions may be indicated. Fluid replacement given intravenously or orally to correct or prevent hydration at 1 to 1.5 times the maintenance requirement is recommended. Close monitoring of fluid status is essential as aggressive hydration, particularly with sodium-containing fluids, can lead to volume overload, ACS, and heart failure.[4,10,13,22]

TABLE 124-6

Management of Acute Pain of Sickle Cell Disease

Principles
1. Treat underlying precipitating factors 2. Avoid delays in analgesia administration a. Initiate analgesic within 30 minutes of triage or 60 minutes of registration 3. Use pain scale to assess severity 4. Choice and dose of initial analgesic should be based on the home regimen, previous pain pattern, history of response, current status, and other medical conditions. The following initial dosages may be considered if an individualized plan unavailable: a. Morphine (IV): 0.1-0.15 mg/kg/dose for less than 50 kg; 5-10 mg/dose for greater than 50 kg b. Hydromorphone (IV): 0.015-0.02 mg/kg for less than 50 kg; 1.5 mg/dose for greater than 50 kg c. Ketorolac 0.5 mg/kg IV up to 30 mg/dose 5. Schedule pain medication; avoid as-needed dosing 6. Provide rescue dose for breakthrough pain 7. If adequate pain relief can be achieved with one or two doses of morphine, consider outpatient management with a weak opioid; otherwise hospitalization is needed for parenteral analgesics 8. Frequently assess to evaluate pain severity and adverse drug reactions; titrate dose as needed 9. Treat adverse effects of opioids as part of pain management 10. Consider nonpharmacologic intervention (eg, relaxation techniques, guided imagery, deep breathing) 11. Transition to oral analgesics as the patient improves; choose an oral agent based on previous history, anticipated duration, and ability to swallow tablets; if sustained-release products are used, a product with a rapid onset is also needed for breakthrough pain
Analgesic regimens
Mild-to-moderate pain: nonopioid ± weak opioid
Moderate-to-severe pain: weak opioid or low dose of a strong opioid ± nonopioid
Severe pain: strong opioid + nonopioid
Other adjunct therapy
Hydration, heating pads, relaxation, and distraction
Nonopioid analgesic including transdermal lidocaine and NSAIDs
Laxatives for constipation
Antihistamine for itching
Antiemetics for nausea or vomiting

Data from References [4,10,11,79-81], and [82].

The frequency and severity of acute pain episodes associated with SCD are variable. Pain should be assessed and analgesic therapy should be tailored for each patient and each individual episode. Several verbal and nonverbal pain assessment tools are available to measure pain intensity, but these tools have not been validated for sickle cell pain. Pain scales validated for use in children, such as the Wong-Baker FACES scale, should be used in pediatric patients with SCD pain. The healthcare provider should choose one tool appropriate for age and use it to assess pain. However, numeric scales alone should not be the only assessment of pain severity. Other useful information to guide the choice of analgesics includes previous effective agents and their dosages, response to therapy and previous clinical course, and duration of pain episodes.[10,83,84] Individualized patient-specific protocols and standardized pathways improve the quality of pain management.[79,81,85]

8 Aggressive therapy that relieves pain and enables the patient to attain maximum functional ability should be initiated in patients with acute pain. Mild-to-moderate pain should be treated with nonsteroidal anti-inflammatory drugs (NSAIDs) or acetaminophen, unless there are contraindications to their use. Ketorolac may be useful for patients requiring intravenous therapy. Because of the increased risk of gastrointestinal bleeding, the duration of therapy should be limited to 5 days or less. NSAID use has been associated with acute nonreversible kidney failure in a patient with SCD and should be done with caution and monitoring of renal function.[82] When acetaminophen is used, it is important to monitor the total dose of acetaminophen administered because of the risk of hepatic toxicity. Patients may also be receiving the agent for fever or another acetaminophen-containing product for pain. If mild-to-moderate pain persists, an opioid can be added.[10,22,79,80,83]

Severe pain should be treated aggressively until the pain is tolerable. Commonly used opioids include morphine, hydromorphone, fentanyl, and methadone. The weak opioids, codeine, and hydrocodone are used to manage mild-to-moderate pain usually in the outpatient setting. Some patients have clinically demonstrated inadequate relief to analgesic dosing with codeine. Some individuals who failed oral therapy with codeine were found to have a polymorphism in the *CYP2D6* gene resulting in a poor metabolizer phenotype. The CYP2D6 enzyme mediates the metabolism of codeine to morphine.[83,86] These results can lead to early discontinuation of codeine analgesics if no response is seen after their first dose and use of alternative oral analgesics for the treatment of pain at home. Meperidine has no advantages as an analgesic and many disadvantages. Meperidine toxicity is caused by accumulation of the metabolite normeperidine, which can cause adverse drug reactions in the central nervous system, ranging from dysphoria to seizures. Effective combination therapy, such as an NSAID and an opioid, can enhance analgesic efficacy while decreasing adverse drug reactions.

Both prior history and current assessment should be considered in the management of acute sickle cell pain. For patients whose typical pain improves in a short time, preparations with a short duration of action are appropriate. For patients whose pain requires many days to resolve, sustained-release preparations combined with a short-acting product for breakthrough pain are more appropriate. If the patient has been on long-term opioid therapy at home, tolerance can develop. In these cases, acute pain should be treated with an opioid of different potency or a larger dose of the same medication. Low dose ketamine has been evaluated as an adjunct therapy for individuals with severe pain despite high dose opioid therapy. The consensus guidelines on the use of intravenous ketamine for acute pain management recommends that ketamine may be considered for opioid-dependent or -tolerant patients with acute or chronic sickle cell pain. The dosing range is not well defined but the guideline recommends the bolus dose not to exceed 0.35 mg/kg and the infusion rate not to exceed 1 mg/kg/hr.[87]

Intravenous opioids provide a rapid onset of action and therefore are preferred for severe pain. Intramuscular injections should be avoided. Children may actually deny pain due to fear of injections. Analgesics should be titrated to pain relief. In patients with continuous pain, the analgesic should be given as a scheduled dose or continuous infusion. Continuous infusion has the advantage of less fluctuation of blood levels between dosing intervals. As needed dosing is only indicated for breakthrough pain. Patient-controlled analgesia (PCA) is commonly prescribed for severe pain episodes. When used properly, PCA allows patients to have control over pain therapy and minimizes the lag time between perception of pain and administration of analgesics. PCA use reduces the cumulative dosage required for pain control. Another route of administration to produce rapid pain relief is intranasal administration of an opioid such as fentanyl. The transdermal fentanyl patch has also been used successfully, but its role in sickle cell acute pain crisis is unclear because of its slow onset of pain relief (12-16 hours) and fixed dosage form, which makes it difficult to titrate the dose.[4,10,11,13,80,83]

Chronic Sickle Cell Pain

As the number of adults living with SCD increases due to improved survival, the prevalence of disease morbidities including chronic pain also increases. As outpatients, 55% of adults reported pain in more than half of the days and 29% of adults reported pain on 95% of the days. The 2014 Export Panel Report described pain as chronic when it lasts more than 3 months. Diagnostic criteria for chronic SCD pain syndrome are available.[88]

Treatment of chronic pain in SCD requires an interprofessional team approach. Most physicians with expertise in treating SCD follow established guidelines for chronic pain. Much of the research has focused on the prevention of pain and the management of acute pain episodes. Central sensitization, neurogenic inflammation, and peripheral neural sensitization have been hypothesized to play a role in the development of chronic SCD pain.[34,40] The evidence supports other medications such as selective serotonin reuptake inhibitors, serotonin–norepinephrine reuptake inhibitors, and anticonvulsants commonly used to treat chronic pain in patients with SCD. In a pilot study, pregabalin reduced pain and improved quality of life scores.[89] Nonpharmacological interventions such as acupuncture, massage, cognitive behavioral therapy, and relaxation therapy have also been used as adjunct therapy.

Episodic Transfusions for Acute Complications

Indications for acute blood transfusion include: (1) acute exacerbation of baseline anemia, such as aplastic crisis if the anemia is severe, hepatic or splenic sequestration, or severe hemolysis; (2) ACS, stroke, intrahepatic cholestasis, or acute multisystem organ failure; and (3) preparation for procedures that require the use of general anesthesia.[22] Acute transfusion is not indicated for priapism, uncomplicated pain or asymptomatic anemia. Simple transfusion or partial exchange transfusion can be used, though red cell exchange has superior outcomes when compared to simple transfusion in overt stroke. If simple transfusion is used, volume overload leading to congestive heart failure can occur if anemia is corrected too rapidly in patients with severe anemia. Acute increases in hemoglobin level to greater than 10 g/dL (100 g/L; 6.21 mmol/L) can cause hyperviscosity and should be avoided.[3,22]

Infection and Fever

Fever in a patient with SCD should be considered a medical emergency with rapid administration of intravenous antibiotics due to the risk of overwhelming sepsis. Patients with SCD should be evaluated as soon as possible for any fever greater than 38.5°C (101.3°F). Criteria for hospitalization include an infant younger than 1 year, history of previous bacteremia or sepsis, temperature greater than 39.5°C (103.1°F), WBC greater than 30,000 cells/mm^3 (30×10^9/L) or less than 5,000 cells/mm^3 (5×10^9/L), platelets less than 100,000 cells/mm^3 (100×10^9/L), or evidence of other acute complications or toxic appearance. Outpatient management can be considered in older nontoxic children with reliable family caregivers. Antibiotic choice should provide adequate coverage for encapsulated organisms.[4,22,32,90]

⑦ Ceftriaxone should be used for outpatient management because it provides coverage for 24 hours unless the patient has received ceftriaxone in the previous 8 weeks and then ampicillin should be given due to ceftriaxone-induced hemolysis.[91] For patients with cephalosporin allergy, clindamycin can be used. Vancomycin should be considered for acutely ill children or if *Staphylococcus* is suspected. Vancomycin trough levels should be closely monitored to ensure therapeutic levels are attained while minimizing the 4.5-fold greater risk for acute kidney injury with this antibiotic.[92,93] A macrolide antibiotic should be added if *M. pneumoniae* is suspected such as in ACS. Penicillin prophylaxis should be discontinued while the patient is receiving broad-spectrum antibiotics. Acetaminophen or ibuprofen can be used for fever control. Increased fluid requirement may be present because of poor oral intake and/or increased insensible losses contributing to dehydration.[13,32]

Cerebrovascular Accidents

Patients with acute neurologic events must be hospitalized and monitored closely. Physical and neurologic examination should be performed every 2 hours. Acute treatment for children should include exchange transfusion to maintain Hb at about 10 g/dL (100 g/L; 6.21 mmol/L) and HbS less than 30%, anticonvulsants for patients with a seizure history, and therapy for increased intracranial pressure if needed. Chronic transfusion therapy should be initiated for children with ischemic stroke as discussed earlier. In adults presenting with ischemic stroke related to atherosclerotic disease and not occlusion by sickled red cells, thrombolytic therapy should be administered if it is less than 3 hours since the onset of symptoms.[13,22,36,94]

Acute Chest Syndrome

All patients with SCD admitted for a vasoocclusive crisis should use incentive spirometry frequently (eg, at least every 2 hours while awake) to reduce atelectasis development. In addition, proper management of pain is important. The goal is to provide relief while avoiding analgesic-induced hypoventilation. Appropriate fluid therapy is important as overhydration can cause pulmonary edema. For patients who develop ACS, early use of broad-spectrum antibiotics, including a macrolide or quinolone in adults, is recommended. Infection is a common cause of ACS and can involve gram-positive, gram-negative, or atypical bacteria as well as viral infection. Oxygen therapy is indicated for all patients who are hypoxic. In a patient with a history of reactive airway disease, asthma or wheezing on examination, a trial of bronchodilators is appropriate. Transfusions are indicated for severe ACS with worsening hypoxia and increased work of breathing.[13,33,34]

Steroids can decrease inflammation and endothelial cell adhesion. Their use can decrease the duration of hospitalization and need for transfusions and other supportive care but can also increase the readmission rate for other SCD–related complications. Another potential therapy is NO, which relaxes and dilates blood vessels. Its hematologic effects include inhibition of platelet aggregation and reduction in the polymerization tendency of HbS. Marked improvement of pulmonary status and cardiac output were reported in some patients with ACS.[33,34]

Priapism

Stuttering priapism, episodes that last a few minutes to 2 hours, may resolve spontaneously with exercise, warm bath, and oral analgesics. Prolonged episodes lasting more than 2 to 3 hours require prompt medical attention. The initial goals of treatment are to provide appropriate analgesic therapy, reduce anxiety, produce detumescence, and preserve testicular function and fertility. Treatment given within 4 to 6 hours can usually reduce erection. Aggressive hydration and adequate pain control should be initiated. Heat (hot water bottles, hot packs, or sitz baths) can provide comfort without precipitating a pain crisis. Although transfusions have been given to these patients, they are not recommended because they are not efficacious and may be associated with severe neurologic sequelae if the Hb concentration is raised too precipitously.[40,95]

Clinicians have used both vasoconstrictors and vasodilators in the treatment of priapism. Vasoconstrictors, such as diluted phenylephrine (10 mcg/mL) or epinephrine (1 mcg/mL), are thought to work by forcing blood out of the corpus cavernosum into the venous return. In one uncontrolled, open-label study, aspiration followed by intra-penile irrigation of epinephrine was well tolerated and effective in 37 of 39 episodes. The procedure should be performed by a urologist with experience in the treatment of priapism.[13,40,95]

Vasodilators, such as terbutaline and hydralazine, relax the smooth muscle of the vasculature. This relaxation allows oxygenated arterial blood to enter the corpus cavernosum, which displaces or washes out the damaged sickle cells. Terbutaline has been used to treat priapism, but it has not been formally studied in patients with SCD.[40,95] Antiandrogens, bicalutamide and finasteride, have been used in SCD for treatment of recurrent or refractory priapism without major adverse drug reactions.[95] Surgical interventions used in severe refractory priapism have included a variety of shunt procedures. These surgical procedures have been successful in some cases, but they have a high failure rate and potentially serious complications, which include impotence, skin sloughing, cellulitis, and urethral fistulas.[40,95]

Modalities to prevent priapism are limited and not well studied. Pseudoephedrine (30 or 60 mg/day given orally at bedtime) and leuprolide, a gonadotropin-releasing hormone, have been used. In one case report, a single oral sildenafil dose at onset of priapism aborted episodes. However, long-term studies of sildenafil show an increase in the frequency of pain episodes.[40,95] The results of a randomized, double-blind, placebo-controlled trial to evaluate efficacy and safety of sildenafil at a dose of 50 mg/day to prevent recurrent episodes was inconclusive partly due to a small sample size.[96] Hydroxyurea promotes NO release but its effect on priapism has not been established.[97] Some clinicians transfuse patients to maintain an HbS level less than 30% to prevent recurrent priapism. Duration of such regimens should be limited to 6 to 12 months. Long-term chronic transfusions to prevent priapism are not recommended.[22,95]

Aplastic Crisis

Treatment of aplastic crisis is primarily supportive. Most patients recover spontaneously within 5 to 10 days. The only treatment may be blood transfusion if the anemia is severe or symptomatic. The reticulocyte count is used to detect the suppression of RBC production and the need for transfusion. The most common cause, parvovirus B19, is contagious and infected patients should be placed in isolation. In addition, contact with pregnant healthcare providers should be avoided because parvovirus infection during the mid-trimester of pregnancy can result in hydrops fetalis and stillbirth.[4,13,32]

Splenic Sequestration

Splenic sequestration is a major cause of mortality in young children with SCD. The sequestration of RBCs in the spleen can result in a rapid drop of hemoglobin, leading to hypovolemia, shock, and death. Immediate treatment with fluid resuscitation and blood transfusions is indicated to correct hypovolemia. Broad-spectrum antibiotic therapy, which includes coverage for *Streptococcus pneumoniae* and *H. influenzae*, can also be beneficial if the patient is febrile as infection can precipitate sequestration.[1,4,22]

Recurrent episodes occur in about half of patients and are associated with increased mortality. Options for the management of recurrence include observation and splenectomy.[22] Increased risk of invasive infection after splenectomy is a concern in young children, but most experts agree individuals with HbSS develop splenic dysfunction as early as 6 months of age and have acquired asplenia by 5 years of age and by 10 to 12 years for those with HbSC. Splenectomy is probably indicated, even after a single sequestration crisis, if that sequestration was life-threatening. Splenectomy should be considered after repetitive episodes, even if they are less serious. For children younger than 2 years of age, some experts recommend chronic blood transfusions to prevent sequestration and delay splenectomy until the age of 2 years, when the risk of post splenectomy septicemia is lower and pneumococcal vaccination has been completed. Splenectomy should also be considered for patients with chronic hypersplenism.[4,13,22,35]

EVALUATION OF THERAPEUTIC OUTCOMES

⑨ For infants younger than 1 year, medical evaluations every 2 to 4 months are recommended. Beyond 2 years of age, evaluation can be extended to every 6 to 12 months with modifications depending on the severity of the illness. Routine laboratory evaluation includes complete blood cell counts and reticulocyte counts every 3 to 6 months up to 2 years of age, then every 6 to 12 months; HbF level should be screened annually until 2 years of age. The laboratory evaluation should be performed every 2 to 3 months if the patient is receiving hydroxyurea therapy. Renal, hepatobiliary, and pulmonary function should be evaluated annually. TCD screening is recommended to start at age 2 years and to be performed annually for children with HbSS and HbSβ$_0$. Ophthalmologic examination to screen for retinopathy is recommended at around age 10 to 12 years for those with HbSC and 14 years for HbSS. In patients with recurrent ACS, pulmonary function tests should be done to establish baseline values and identify declines in lung function as well as an evaluation to screen for lower airway hyper-responsiveness.

Immunizations and prophylactic antibiotics must be given. When infections do occur, appropriate antibiotic therapy should be initiated, and the patient should be monitored for laboratory and clinical improvement. The effectiveness of hydroxyurea can be measured as a decrease in the number, severity, and duration of sickle cell pain episodes. HbF concentrations or MCV values can be used as a biomarker of the patient’s response to therapy. When painful episodes do occur, the effectiveness of analgesics can be measured by subjective assessments made by the patient and healthcare practitioners. The success of poststroke blood transfusions can be measured by clinical progression or the occurrence of subsequent strokes.

CONCLUSION

SCD is an inherited disorder in the β-globin gene and involves multiple organ systems. Common complications include vasoocclusive pain crisis, ACS infection, stroke, pulmonary hypertension, etc. Several pharmacologic therapies are available. Hydroxyurea, L-glutamine, and crizanlizumab decrease the frequency of pain crises. Voxelotor increases the Hb level. Transfusion therapy and allogeneic HSCT are also used to manage SCD. Changes in organ function and other healthcare maintenance issues need to be monitored regularly.

ABBREVIATIONS

ACS	acute chest syndrome
DHTR	delayed hemolytic transfusion reactions
GVHD	graft-versus-host disease
HbA	hemoglobin A
HbAS	one normal (hemoglobin A) and one sickle cell hemoglobin (hemoglobin S) gene
HbC	hemoglobin C
HbF	fetal hemoglobin
HbS	sickle cell hemoglobin

HbSβ$^+$-thal	hemoglobin sickle cell β$^+$-thalassemia
HbSβ^0-thal	hemoglobin sickle cell β^0-thalassemia
HbSC	one sickle cell hemoglobin (hemoglobin S) gene and one hemoglobin C gene
HbSS	homozygous sickle cell hemoglobin (hemoglobin S)
HLA	human leukocyte antigen
HPFH	hereditary persistence of fetal hemoglobin
HSCT	hematopoietic stem cell transplantation
ISC	irreversibly sickled cell
MCV	mean corpuscular volume
MRI	magnetic resonance imaging
MSH	Multicenter Study of Hydroxyurea in Sickle Cell Anemia
NO	nitric oxide
NSAID	nonsteroidal anti-inflammatory drug
NT-pro-BNP	N-terminal pro-brain natriuretic peptide
PAH	pulmonary artery hypertension
PCA	patient-controlled analgesia
PCV13	13-valent pneumococcal conjugate vaccine
PPSV23	23-valent pneumococcal polysaccharide vaccine
RBC	red blood cell
SCA	sickle cell anemia
SCD	sickle cell disease
SCT	sickle cell trait
TCD	transcranial Doppler ultrasound
VTE	venous thromboembolism
WBC	white blood cell

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements is incorrect?

   A. Sickle cell disease is a hereditary disorder involving abnormal hemoglobin.

   B. Patients with sickle cell trait usually are asymptomatic but can become symptomatic in extreme conditions.

   C. Sickle cell disease is only seen in those with African ancestry.

   D. The primary clinical manifestations of sickle cell disease are hemolysis and vasoocclusion.

   E. Patients with a higher level of fetal hemoglobin generally have milder disease.

2. Patients with sickle cell anemia have an increased risk of which of the following infections:

   A. *Streptococcus pneumoniae*

   B. *Candida* species

   C. *Aspergillus* species

   D. *Pseudomonas* species

   E. *Enterobacter* species

3. Prevention of pneumococcal infection in sickle cell disease includes:

   A. 13-Valent pneumococcal conjugate vaccine
   B. Oral penicillin
   C. 23-Valent pneumococcal polysaccharide vaccine
   D. All of the above
   E. None of the above

4. The appropriate penicillin prophylaxis regimen is:
   A. Penicillin 125 mg twice daily by mouth from 5 years of age to adolescent
   B. Penicillin 125 mg once a day by mouth begin at diagnosis until 5 years of age
   C. Penicillin 125 mg twice a day by mouth begin at diagnosis until 3 years of age, then 250 mg twice daily until age 5
   D. Penicillin 125 mg twice a day by mouth until the first dose of pneumococcal vaccine
   E. Penicillin 250 mg twice a day by mouth begin at diagnosis until the first dose of pneumococcal vaccine then once daily

5. Hydroxyurea is useful in the management of sickle cell disease because:
   A. It is a chemotherapeutic agent.
   B. It increases fetal hemoglobin production.
   C. It suppresses bone marrow production of sickle hemoglobin.
   D. It inhibits the cation transport in red blood cell membrane.
   E. It has the potential to cure the disease.

6. Which of the following statements is correct?
   A. Hydroxyurea is useful in the management of sickle cell disease because the agent is efficacious in reducing pain episodes and has no toxicities.
   B. Hydroxyurea is preferred over deferoxamine because of its sustained effect on fetal hemoglobin and lack of adverse drug reactions with long-term use.
   C. Hydroxyurea reduces painful crises but close monitoring is needed because of its effect on the bone marrow.
   D. Deferasirox is the drug of choice for fetal hemoglobin induction because of its safety profile.
   E. Penicillin prophylaxis can be discontinued once a fetal hemoglobin inducer is initiated.

7. The appropriate management of sickle cell patients presenting with fever includes the following except:
   A. Cefotaxime or ceftriaxone. Vancomycin should also be considered in acutely ill individuals.
   B. Ibuprofen or Tylenol for fever.
   C. Fluid.
   D. Frequent monitoring.
   E. Pneumococcal vaccine.

8. The primary indication for chronic transfusion program is:
   - A. Prevention of infection
   - B. Prevention of organ damage
   - C. Lack of fetal hemoglobin response to hydroxyurea
   - D. Bone marrow suppression secondary to hydroxyurea
   - E. Prevention of stroke
9. Patients admitted with signs and symptoms of acute chest syndrome should:
   - A. Avoid opioid analgesics because those agents may suppress ventilation
   - B. Receive twice maintenance fluid to prevent dehydration from hyperventilation
   - C. Not receive bronchodilators because those agents cause excessive relaxation leading to the collapse of the airway
   - D. Receive appropriate pain management, oxygen, balanced fluid, and antimicrobial agents
   - E. Be given corticosteroids because the agents reduce hospital stay, need for transfusions, and supportive care and readmission
10. The most common cause for an aplastic crisis is:
    - A. Pneumococcal infection
    - B. Delayed hemolytic transfusion reactions occurred after transfusion
    - C. Parvovirus B19
    - D. Sequestration of red blood cells in the spleen
    - E. Splenectomy
11. Which of the following is true in regard to the management of vasoocclusive pain episodes?
    - A. Hydration and aggressive analgesia are the primary treatment. Analgesic therapy should be individualized.
    - B. Opioid analgesics should be kept at a minimum because patients become addicted to those agents.
    - C. Patients who require opioid analgesia more than 24 hours are drug-seeking.
    - D. All patients with pain episodes should be hospitalized.
    - E. Fluid restriction should be initiated to prevent fluid overload.
12. Analgesic choices for sickle cell patients with mild-to-moderate pain include the following except:
    - A. Nonsteroidal anti-inflammatory drugs (NSAIDs)
    - B. Acetaminophen
    - C. Opioid analgesics
    - D. Combination of NSAIDS and opioid analgesics
    - E. Intramuscular meperidine

13. Patient controlled analgesia (PCA) is useful in the management of sickle cell pain crisis because

    A. It limits the amount of opioids that can be delivered to the patient; therefore, avoiding confrontation with the patient.

    B. This method of delivery increases the duration of action.

    C. Intramuscular administration of pain medications should be avoided, especially for young children.

    D. It gives the patient control over the analgesic therapy.

    E. It minimizes addiction potential.

14. Newborn screening for sickle cell disease can be cost-effective.

    A. True

    B. False

15. The available curative therapy for sickle cell disease is:

    A. HbF inducer

    B. Hematopoietic stem cell transplant

    C. Corticosteroids

    D. Vaccines

    E. Glutamine

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** SCD can be found in sub-Saharan Africa, Arabian Peninsula, the Indian subcontinent, and the Mediterranean region. The prevalence of SCD is highest in sub-Saharan Africa.

2. **A.** Individuals with SCD are susceptible to encapsulated organisms.

3. **D.** Penicillin prophylaxis should be initiated in patients with HbSS or HbSβ^0-thal in addition to vaccines.

4. **C.** Recommended regimen.

5. **B.** Hydroxyurea is a disease modifying agent that increases fetal hemoglobin, thus reducing HbS polymerization.

6. **C.** Hydroxyurea is a chemotherapeutic agent that requires monitoring.

7. **E.** Pneumococcal vaccine is not for acute treatment of streptococcal infection.

8. **E.** Transfusion is indicated for both primary and secondary stroke prevention.

9. **D.** Overhydration can cause pulmonary edema and exacerbate respiratory distress. Infection is a common cause of acute chest syndrome; therefore, it should be managed appropriately. The goal of pain management is to provide pain relief and maintain respiratory status.

10. **C.** Bone marrow can become hypoplastic and is most often associated with a viral infection.

11. **A.** Principle on pain management is individualized regimen.

12. **E.** Meperidine can develop toxicity caused by the accumulation of the metabolite normeperidine that can cause adverse drug reactions in the

central nervous system. IM is not the recommended route, especially in children.

13. **D.** Giving patients control of their pain management is beneficial. PCA reduces overall opioid needs.

14. **A.** In the United States, newborn screen for SCD is performed in all 50 states.

15. **B.** Hematopoietic stem cell transplant is the only available curative therapy for individuals with SCD. Gene therapy is a promising alternative but is early in development and only available through early phase research studies.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 127: Antimicrobial Regimen Selection

Katie B. Olney; David S. Burgess

KEY CONCEPTS

KEY CONCEPTS

① Every attempt should be made to obtain specimens for culture and sensitivity testing prior to initiating antibiotics.

② Empirical antibiotic therapy should be based on knowledge of likely pathogens for the site of infection, information from patient history (eg, recent hospitalizations, work-related exposure, travel, and pets), and local susceptibility.

③ Patients with delayed dermatologic reactions (ie, rash) to penicillin generally can receive cephalosporins. Patients with type I hypersensitivity reactions (ie, anaphylaxis) to penicillins should not receive cephalosporins. Alternatives to the β-lactam antimicrobials include aztreonam, quinolones, sulfonamide antibiotics, or vancomycin based on type of coverage indicated.

④ Renal function should be considered for every patient who is to receive antibiotics. Hepatic function should be considered for drugs eliminated through the hepatobiliary system, such as clindamycin, erythromycin, and metronidazole.

⑤ All concomitant drugs and nutritional supplements should be reviewed when an antibiotic is added to a patient's therapy to ensure drug-drug interactions will be avoided.

⑥ Combination antibiotic therapy may be indicated for polymicrobial infections (eg, intra-abdominal and gynecologic infections), to produce synergistic killing, or to prevent the emergence of resistance.

⑦ All patients receiving antibiotics should be monitored for resolution of infectious signs and symptoms (eg, decreasing temperature and white blood cell count) and adverse drug events.

⑧ Antibiotics with the narrowest effective spectrum of activity are preferred. Antibiotic route of administration should be evaluated daily, and conversion from IV to oral therapy should be attempted as signs of infection improve for patients with functioning GI tracts (general exceptions are endocarditis and CNS infections).

⑨ Patients not responding to an appropriate antibiotic treatment in 2 to 3 days should be reevaluated to ensure (a) the correct diagnosis, (b) that therapeutic drug concentrations are being achieved, (c) that the patient is not immunosuppressed, (d) that appropriate source control has been achieved (ie, abscess and foreign body), or (e) that resistance has not developed.

⑩ The main goals of antimicrobial stewardship programs (ASPs) are to optimize antimicrobial selection, dosing, duration, and route of administration while minimizing adverse drug events and the emergence of antimicrobial resistance.

BEYOND THE BOOK

BEYOND THE BOOK

KS is a 65-year-old woman with a past medical history significant for uterine cancer and total abdominal hysterectomy, for which they received radiation and chemotherapy. They present to the emergency department with complaints of nausea, vomiting, and flank pain. Their vital signs and laboratory values are as follows:

Laboratory Values
C-reactive protein: 224 mg/dL (2,240 mg/L)
WBC: 22,600 cells/mm^3 (22.6 × 10^9 /L)
Bands: 10%

Vitals
Blood pressure: 95/58
Temperature: 39.4°C (103 °F)
Heart rate: 136 beats/min

1. Which of the following statements regarding microbiologic studies is false?
   A. Obtaining cultures prior to administration of antimicrobial therapy may improve culture yield.
   B. Ideally two sets of blood cultures should be obtained peripherally from two different sites 1 hour apart.
   C. Coagulase-negative staphylococci recovered from blood cultures always warrant antimicrobial treatment.
   D. Urine cultures should be evaluated in conjunction with results of the urinalysis to confirm infection.
2. Which of the following is an important consideration when selecting empiric antimicrobial therapy for this patient?
   A. Prior antimicrobial use
   B. Site of infection and the organisms most likely present
   C. Prior knowledge of colonization or infections
   D. All of the above
3. Which of the following criteria must be met prior to transitioning a patient to oral antibiotic therapy?
   A. Re-culture twice daily to ensure adequate microbiological cure
   B. Lack of fever for 8 to 24 hours
   C. Resolution of electrolyte abnormalities
   D. Decrease in C-reactive protein

INTRODUCTION

Antimicrobials are among the most widely used classes of drugs.[1] In the United States, expenditures for antimicrobial agents exceed $8 billion annually. Approximately 20% to 50% of inpatient antibiotic use, 40% to 75% of nursing home antibiotic use, and 30% of outpatient antibiotic use is considered unnecessary or inappropriate.[2] The use of antibiotics is the main driver in creating selective pressure for the emergence of antimicrobial resistant pathogens; nevertheless, antibiotic overuse remains common. Selecting appropriate antimicrobial agent(s) to treat an infection has proven to be a challenging task.[3] Although the choice of a single agent or a combination of agents should be individualized for each patient, certain general principles of therapy should guide the selection of specific drugs (Table 127-1).

TABLE 127-1

Systematic Approach for Selection of Antimicrobials

Confirm the presence of infection Careful history and physical examination Signs and symptoms Predisposing factors
Identification of the pathogen (see Chapter e126, “Laboratory Tests to Direct Antimicrobial Pharmacotherapy”) Collection of infected material Stains Serologies Culture and sensitivity
Selection of presumptive therapy considering every infected site Host factors Drug factors
Monitor therapeutic response Clinical assessment Laboratory tests Assessment of therapeutic failure

The initial selection of antimicrobial therapy is nearly always empirical, which is prior to documentation and identification of the offending organism. Infectious diseases generally are acute, and a delay in antimicrobial therapy can result in serious morbidity or even mortality. Thus, empirical antimicrobial therapy selection should be based on information gathered from the patient’s history and physical examination and results of Gram stains or of rapidly performed tests on specimens from the infected site. This information, combined with knowledge of the most likely offending organism(s) and an institution’s local susceptibility patterns, should result in a rational selection of antibiotics to treat the patient. This chapter introduces a systematic approach to the selection of antimicrobial therapeutic regimens.

CONFIRMING THE PRESENCE OF INFECTION

An infectious disease diagnosis is determined by assessing the presence of signs and symptoms of an infection, determining the site of infection, and establishing a microbiological diagnosis, when possible.

Fever

Aberrations of temperature reaching >38°C (100.4°F) or <36°C (96.8°F) are indicative of systemic inflammation, and may often be seen in patients presenting with infectious disease processes. Body temperature is controlled by the hypothalamus. In addition, the circadian rhythm, a built-in temperature cycle, is also operational. The daily temperature rhythm can vary for each individual. In a healthy person, the internal thermostat is set between the morning low temperature and the afternoon peak as controlled by the circadian rhythm. During fever, the hypothalamus is reset at a higher temperature level.

Fever is defined as a controlled elevation of body temperature above the normal range. The average normal body temperature range taken orally is 36.7°C to 37°C (98°F–98.6°F). Body temperatures obtained rectally generally are 0.6°C (1°F) higher and axillary temperatures are 0.6°C (1°F) lower than oral temperatures, respectively. Skin temperatures are also less than the oral temperature but can vary depending on the specific measurement method. Fever can be a manifestation of disease states other than infection. Collagen vascular (autoimmune) disorders and several malignancies can have fever as a manifestation. Fever of unknown or undetermined origin is a diagnostic dilemma and is reviewed extensively elsewhere.[4]

Many drugs have been identified as causes of fever. *Drug-induced fever* is defined as persistent fever in the absence of infection or other underlying condition. The fever must coincide temporally with the administration of the offending agent and disappear promptly on its withdrawal, after which the temperature remains normal. Possible mechanisms of drug-induced fever are either a hypersensitivity reaction or development of antigen–antibody complexes that result in the stimulation of macrophages and the release of interleukin 1 (IL-1). While fever is not a common drug effect (accounting for no more than 5% of all drug reactions), it should be suspected when obvious reasons for fever are not present. Almost any medication can produce fever, but β-lactam antibiotics, anticonvulsants, allopurinol, hydralazine, nitrofurantoin, sulfonamides, phenothiazines, and methyldopa are responsible more often than others.

Noninfectious etiologies of fever can be referred to as “false-positives.” Although these certainly can confuse the clinician, even more troublesome are false-negatives: the absence of fever in a patient with signs and symptoms consistent with an infectious disease. Careful questioning of the patient or family is vital to assess the ingestion of any medication that can mask fever (eg, aspirin, acetaminophen, nonsteroidal anti-inflammatory agents, and corticosteroids). The use of antipyretics should be discouraged during the treatment of infection unless absolutely necessary because they can mask a poor therapeutic response. Moreover, elevated body temperature, unless very high (greater than 40.5°C [105°F]), is not harmful and may be beneficial.

White Blood Cell Count

Most infections result in elevated white blood cell (WBC) counts (leukocytosis) because of the increased production and mobilization of granulocytes (neutrophils, basophils, and eosinophils), lymphocytes, or both to destroy invading microbes. The generally accepted range of normal values for WBC counts is between 4,000 and 10,000 cells/mm^3 (4×10^9 and 10×10^9/L). Values above or below this range hold important prognostic and diagnostic value.

Bacterial infections are associated with elevated granulocyte counts, often with immature forms (band neutrophils) seen in peripheral blood smears. Mature neutrophils are also referred to as *segmented neutrophils* or *polymorphonuclear* (PMN) *leukocytes*. The presence of immature forms (left shift) is an indication of an increased bone marrow response to the infection. With infection, peripheral WBC counts can be very high, but they are rarely higher than 30,000 to 40,000 cells/mm^3 (30×10^9/L to 40×10^9/L). Because leukocytosis indicates the normal host response to infection, low leukocyte counts after the onset of infection indicate an abnormal response and generally are associated with a poor prognosis.

The most common granulocyte defect is neutropenia, a decrease in absolute numbers of circulating neutrophils. A thorough description of the consequences of neutropenia is given in Chapter 145, “Infections in Immunocompromised Patients.” Lymphocytosis, even with normal or slightly elevated total WBC counts, generally is associated with tuberculosis and viral or fungal infections. Increases in monocytes can be associated with tuberculosis or lymphoma, and increases in eosinophils can be associated with allergic reactions to drugs or infections caused by metazoa. Many types of infections can be accompanied by a completely normal WBC count and differential.

Local Signs

The classic signs of pain and inflammation can manifest as swelling, erythema, tenderness, and purulent drainage. Unfortunately, these are only visible if the infection is superficial or in a bone or joint. The manifestations of inflammation in deep-seated infections (eg, meningitis, pneumonia, endocarditis, and urinary tract infection) must be ascertained by examining tissues or fluids. For example, the presence of neutrophils in spinal fluid, lung secretions (sputum), or urine is highly suggestive of a bacterial infection.

Symptoms referable to an organ system must be sought out carefully because not only do they help in establishing the presence of infection, but they also aid in narrowing the list of potential pathogens. For example, a febrile patient with complaints of flank pain and dysuria may be presenting with pyelonephritis. In this situation, enteric gram-negative bacilli, especially *Escherichia coli*, are the predominant pathogens. If a febrile patient has no symptoms suggestive of an organ system but only constitutional complaints, the list of possible infectious diseases is lengthy.[4] A febrile individual with cough and sputum production may have a pulmonary infection. What is not so evident, however, is the etiologic organism in this situation, because pneumonia can be bacterial, viral, or fungal in etiology.[5] In this situation, attention to the patient's history and background disease states is important. Even more important is a careful examination of the infected material (in this case sputum) to ascertain the identity of the pathogen.

IDENTIFICATION OF THE PATHOGEN

Microbiological Studies

① Identification and antimicrobial susceptibility of a pathogen are the most important factors in determining the choice of antimicrobial therapy. Generally, infected body materials must be sampled, if at all possible or practical, before or concurrently with institution of any antimicrobial therapy for two reasons. First, a Gram stain of the material might reveal bacteria, or an acid-fast stain might detect mycobacteria or actinomycetes. Second, the premature use of antimicrobials can suppress the growth of pathogens that might result in false-negative cultures results or alterations in the cellular and chemical composition of infected fluids. This is particularly true in patients with vertebral osteomyelitis, urinary tract infections, subacute endocarditis, meningitis, and septic arthritis.[11]

Blood cultures should be performed in the acutely ill febrile patient. Blood culture collection should coincide with sharp elevations in temperature, suggesting the possibility of microorganisms or microbial antigens in the bloodstream. Ideally, blood should be obtained from peripheral sites as two sets (one set consists of an aerobic bottle and one set an anaerobic bottle) from two different sites approximately 1 hour apart to optimize culture yield. In selected infections, bacteremia is qualitatively continuous (eg, endocarditis), so cultures can be obtained at any time.[10]

In addition to the infected materials produced by the patient (eg, blood, sputum, urine, stool, and wound or sinus drainage), other less accessible fluids or tissues must be obtained if they are suspected to be the infected site (eg, spinal fluid in meningitis and joint fluid in arthritis). Abscesses and cellulitic areas also should be aspirated.

When a pathogenic microorganism is identified, the next step for the majority of clinical microbiological laboratories is antimicrobial susceptibility testing (AST) that measures the ability of a select organism to grow in the presence of an antimicrobial agent. These methods are described in detail in Chapter e126. Once a microorganism is identified and its susceptibilities are known, antimicrobial therapy should be tailored to the specific pathogen.

Over the last decade, there has been an explosion in the development of rapid diagnostic methods that provide simultaneous organism identification and resistance marker detection. These methods include nonamplified probe technologies (peptide nucleic-acid-fluorescence in situ hybridization), proteomics, and nucleic acid amplification methods combined with microarray technologies. These tests can significantly reduce time to organism identification; thereby, reducing time to effective antimicrobial therapy. Rapid diagnostic tests reduce overall antimicrobial use, length of hospital stay, and mortality among patients with infectious diseases.[12-16]

Interpreting Results

After a positive Gram stain, culture results, or both are obtained, the clinician must be cautious in determining whether the organism recovered is a true pathogen, a contaminant, or a part of the normal flora (see Chapter e126). The latter consideration is especially problematic with cultures obtained from the skin, oropharynx, nose, ears, eyes, throat, and perineum. These surfaces are heavily colonized with a wide variety of bacteria, some of which can be pathogenic in certain settings. For example, coagulase-negative staphylococci are found in cultures of all the aforementioned sites, yet are seldom regarded as pathogens unless recovered from multiple blood cultures, venous access catheters, or prosthetic devices.

Cultures of specimens from purportedly infected sites that are obtained by sampling from or through one of these contaminated areas might contain significant numbers of the normal flora. For example, asymptomatic bacteriuria, or bacterial colonization of the genitourinary tract in the absence of symptoms, is common even in healthy individuals. The treatment of asymptomatic bacteriuria is an important contributor to inappropriate antimicrobial use and promotion of resistance.[17] Careful consideration of a patient's presenting symptoms, risk factors, and history are essential to discern true infection from colonization..

Particularly problematic are expectorated sputum specimens that must be evaluated carefully by determination of the presence of squamous epithelial cells and leukocytes.[4] A predominance of epithelial cells in sputum specimens reduces the likelihood that recovered bacteria are pathogenic, especially when multiple types of organisms are seen on Gram stain. In contrast, the discovery of leukocytes in large numbers with one predominant type of organism is a more reliable indicator of a valid collection and quality sample. In general, however, sputum evaluation has poor sensitivity and specificity as a diagnostic test.[5]

Gram-staining techniques, culture methods, and serologic identification, as well as susceptibility testing, are discussed in detail in Chapter e126. Emphasis must be placed on the proper collection and handling of specimens and careful assessment of Gram stain or other test results in guiding the clinician toward appropriate selection of initial antimicrobial therapy.[18]

SELECTION OF PRESUMPTIVE THERAPY

② In many instances, empiric therapy must be instituted before microbiological results are available. To select rational antimicrobial therapy for a given clinical situation, a variety of factors must be considered. These include the severity and acuity of the disease, local epidemiology and antibiogram, patient history, host factors, factors related to the drugs used, and the necessity for using multiple agents. In addition, there are generally accepted drugs of choice for the treatment of most pathogens (see Appendix 123-1).

Antibiogram

Drugs of choice are compiled from a variety of sources and are intended as guidelines rather than as specific rules for antimicrobial use. These choices are influenced by local antimicrobial susceptibility data rather than information published by other institutions or national compilations. Each institution should publish an annual summary of antibiotic susceptibilities (antibiogram) for organisms cultured from patients. Antibiograms contain both the number of nonduplicate isolates for common species and the percentage susceptible to the antibiotics tested. To further guide empirical antibiotic therapy, some hospitals publish unit-specific antibiograms in unique patient care areas, such as intensive care units or burn units.

Susceptibility of bacteria can differ substantially among hospitals within a community. For example, the prevalence of hospital-acquired methicillin-resistant *Staphylococcus aureus* (HA-MRSA) in some centers is quite high, whereas in other centers the problem might be nonexistent. This particular situation will influence the selection of therapy for possible *S. aureus* infection, where the clinician must choose either a β-lactam or vancomycin. The problem of differing susceptibilities is not limited only to gram-positive bacteria but also is evident in gram-negative organisms, and all drug classes are affected.

Patient History

Empirical therapy is directed at organisms that are known to cause the infection in question. These organisms are discussed for different sites of infection in Chapters 124–143. To define the most likely infecting organisms, a careful history and physical examination must be performed. The place where the infection was acquired should be determined, for example, the home (community acquired), nursing home environment, or hospital acquired (nosocomial). Nursing home patients can be exposed to potentially more resistant organisms because they are often surrounded by ill patients who are receiving antibiotics. Important considerations when selecting empiric antimicrobial therapy include: (1) prior knowledge of colonization or infections, (2) previous antimicrobial exposure, (3) the site of infection and the most likely pathogens, and (4) local antibiogram and resistance patterns for important pathogens. Other questions to ask infected patients regarding the history of present illness include: (1) Are any other people sick at home, especially children? (2) Are any unusual pets kept in the home? (3) Where are you employed (ie, are you exposed to contaminated meat or infectious biohazards)? and (4) Has there been any recent travel (ie, to endemic areas of fungal infections or developing countries)?

Host Factors

Several host factors should be considered when evaluating a patient for antimicrobial therapy. The most important factors are drug allergies, age, pregnancy, genetic or metabolic abnormalities, renal and hepatic function, site of infection, concomitant drug therapy, and underlying disease states.

Allergy

③ Anaphylactic allergy to an antimicrobial agent generally precludes its use. Careful assessment of allergy histories must be performed because many patients confuse common adverse drug effects (ie, GI disturbance) with true allergic reactions.[19-21] Among the most commonly cited antimicrobial allergies are those to penicillin, penicillin-related compounds, or both. In the absence of complete penicillin skin testing capabilities, a rule of thumb for giving cephalosporins to patients allergic to penicillin is to avoid giving them to patients who give a good history for immediate or accelerated reactions (eg, anaphylaxis, laryngospasm) and to give them under close supervision in patients with a history of delayed reactions, such as a rash.[19] If a gram-negative infection is suspected or documented, therapy with a monobactam may be appropriate because cross-reactivity with other β-lactams is nonexistent, with the exception of isolated cross-reactivity in ceftazidime-allergic patients.

Age

The patient's age is an important factor both in identifying the likely etiologic organism and in assessing pharmacokinetic alterations that may impact the patient's ability to eliminate the drug(s) to be used. The best example of an age determinant of organisms is in bacterial meningitis, where the pathogens differ as the patient grows from the neonatal period through infancy and childhood into adulthood.[6,7]

The impact of age on pharmacokinetics is exemplified in the neonatal population. Neonates have several pharmacokinetic alterations that may lead to variations in drug absorption, distribution, and metabolism. At birth, infants have reduced phase I (eg, cytochrome P450 enzymatic) and phase II (eg, glucuronidation and acetylation) metabolism that develops rapidly throughout the first year of life. Phase II metabolism occurs primarily through sulfation from birth through the first few months of life and is eventually replaced by glucuronidation and acetylation. In addition, neonates have more body water content that results in a larger volume of distribution and variations in gastric emptying time leading to alterations in drug absorption. Each of these alterations result in the need for adjustments in antibiotic dosing regimens.[22] Additional special drug considerations for pediatric patients include availability of dosage formulations (eg, concentration of liquid dosage forms and availability of tablet strengths) and compliance-enhancing features (eg, palatability).

The major physiologic change in persons older than 65 years of age is a decline in the number of functioning nephrons that, in turn, results in decreased renal function.[23] This is usually manifested by an increased incidence of side effects caused by antimicrobials that are eliminated renally.

Pregnancy

During pregnancy, not only is the fetus at risk for drug teratogenicity, but the pharmacokinetic disposition of certain drugs can be altered.[24-27] Penicillins, cephalosporins, and aminoglycosides are cleared from the peripheral circulation more rapidly during pregnancy. This is probably a result of marked increases in intravascular volume, glomerular filtration rate, and hepatic and metabolic activities. The net result is that maternal serum antimicrobial concentrations can be as much as 50% lower during this period than in the nonpregnant state. Increased dosages of certain compounds might be necessary to achieve therapeutic levels during late pregnancy.[26]

Metabolic or Genetic Variation

Inherited or acquired metabolic abnormalities will influence the therapy of infectious diseases in a variety of ways. For example, patients with impaired peripheral vascular flow may not absorb drugs given by intramuscular injection. In addition, certain metabolic states can predispose patients to enhanced drug toxicity. For instance, patients who are phenotypically slow acetylators of isoniaziud are at greater risk for peripheral neuropathy.[28] Patients with severe deficiency of glucose-6-phosphate dehydrogenase can develop significant hemolysis when exposed to such drugs as sulfonamides, nitrofurantoin, nalidixic acid, antimalarials, and dapsone. Although mild deficiencies are found in African Americans, the more severe forms of the disease generally are confined to persons of eastern Mediterranean origin. Another example is the antiretroviral drug abacavir, which is associated with a severe hypersensitivity reaction, consisting of fever, rash, abdominal pain, and respiratory distress. This risk has been associated with the presence of a human leukocyte antigen allele HLA-B*5701. Routine screening for the presence of this allele before initiating treatment with abacavir is a recommendation in the current HIV treatment guidelines. Furthermore, the hepatic cytochrome P450 system is a major pathway for a large number of antimicrobials. While differential host expressions of these enzymes occur, insufficient clinical data are available to recommend routine screening for antimicrobial therapy.

Organ Dysfunction

④ Patients with diminished renal or hepatic function may have pharmacokinetic alterations resulting in altered antibiotic exposure. These alterations often necessitate dose individualization and therapeutic drug monitoring, especially in critically ill populations. Because many of the commonly used antimicrobials are primarily cleared by the kidneys, it is imperative to adjust the dosing regimen as clinically appropriate.[29,30] However, there are many etiologies for altered serum creatinine concentrations aside from renal dysfunction (eg, sepsis, immobility-related cachexia) and inappropriate assessment of these concentrations may lead to inaccurate estimations of glomerular filtration rate (GFR) and creatinine clearance (CrCl).[31] Renal dose adjustment of antibiotics should be delayed for the first 48 hours of illness in patients admitted with acute kidney injury (AKI) being treated for infectious diseases.[32] Clinicians should always consider patient-specific factors, severity of illness, and pathogens of concern when making dose adjustments based on measured serum creatinine concentrations. Nephrotoxic medications (eg, aminoglycosides) are generally avoided in patients with severe liver disease.[33]

Concomitant Drugs

⑤ Any concomitant therapy that the patient is receiving can influence the drug selection, dose, and monitoring. For instance, administration of isoniazid to a patient who is also receiving phenytoin can result in phenytoin toxicity secondary to inhibition of phenytoin metabolism by isoniazid. Furthermore, drugs that possess similar adverse effect profiles can increase the risk for effects (ie, two drugs that cause nephrotoxicity or neutropenia). A detailed review of drug interactions is beyond the scope of this chapter, but an excellent textbook on this subject is available.[34] Lists of potentially severe drug-drug interactions are provided in Table 127-2.

TABLE 127-2

Major Drug–Drug Interactions with Antimicrobials

Antimicrobial	Interacting Agent(s)	Mechanism of Action/Effect	Clinical Management
Aminoglycosides	Neuromuscular blocking agents	Additive toxicity of neuromuscular-blocking agents	Monitor therapy
	Nephrotoxins (N) or ototoxins (O) (eg, amphotericin B [N], cisplatin [N/O], cyclosporine [N], furosemide [O], NSAIDs [N], radiocontrast [N], vancomycin [N])	Additive toxicity	Monitor renal function, obtain regular audiograms for patients receiving prolonged or repeated courses of aminoglycosides
	β-lactams	Aminoglycoside degradation	Separate administration and flush line thoroughly between doses of aminoglycoside and β-lactam therapy
Amphotericin B	Nephrotoxins (eg, aminoglycosides, cyclosporine, foscarnet)	Additive nephrotoxicity	Monitor renal function
Azoles	See Chapter 144		
Foscarnet	Pentamidine IV	Increased risk of severe nephrotoxicity and hypocalcemia	Monitor renal function and serum calcium
Isoniazid	Carbamazepine, phenytoin	Decreased metabolism of carbamazepine and phenytoin, resulting in increased serum concentrations	Monitor for signs and symptoms of phenytoin and carbamazepine and phenytoin toxicity (eg, nausea, vomiting, nystagmus, ataxia)
Macrolides/azalides	Digoxin	Decreased digoxin bioavailability and metabolism	Monitor digoxin SDC

	Theophylline	Decreased metabolism of theophylline	Monitor theophylline SDC
Metronidazole	Ethanol (drugs containing ethanol)	Disulfiram-like reaction	Avoid
Fluoroquinolones	Other QTc-prolonging agents (eg, antiemetics, macrolides, azoles, antidepressants, etc.)	Prolonged QTc interval	Monitor ECG at baseline and periodically while on concomitant QTc-prolonging therapy
	Multivalent cations	Decreased absorption of fluoroquinolone	Separate administration by at least 2 hours
Rifampin	Azoles, cyclosporine, methadone, propranolol, oral contraceptives, tacrolimus, warfarin	Increased of metabolism of interacting agent via rifampin induction of CYP-450 metabolism resulting in decreased serum concentrations	Avoid
Sulfonamides	Sulfonylureas, phenytoin, warfarin	Decreased metabolism of interacting agent resulting in increased serum concentrations	Monitor blood glucose, SDC of interacting agent, and PT
Doxycycline	Multivalent cations	Decreased absorption of tetracycline	Separate administration by at least 2 hours

Concomitant Disease States

Concomitant disease states can influence the selection of therapy. Certain diseases will predispose patients to a particular infectious disease or will alter the type of infecting organism. For example, patients with diabetes mellitus and resulting peripheral vascular disease often develop infections of the lower extremity soft tissue. Moreover, the alterations in peripheral blood flow associated with the disease and perhaps altered immunity make such infections more difficult to treat than in nondiabetics. Patients with chronic lung disease or cystic fibrosis develop frequent pulmonary infections that can be caused by somewhat different microorganisms than are found in otherwise normal hosts.

Patients with immunosuppressive diseases, such as malignancies or acquired immunologic deficiencies, are highly predisposed to infections, and the types of causative or pathogenic organisms can be vastly different from what would be expected (see Chapter 145, “Infections in Immunocompromised Patients”). For instance, patients undergoing chemotherapy for acute forms of leukemia often are profoundly granulocytopenic and are predisposed to infections caused by bacteria and fungi.[35] Patients with acquired immunodeficiency syndrome (AIDS) are more likely to become infected with less common opportunistic pathogens (see Chapter 148, “Human Immunodeficiency Virus”). Many factors predisposing to infection are related to disruption of the host’s integumentary barriers. For example, trauma, burns, and iatrogenic wounds induced in surgery can lead to a substantial risk of infection depending on the severity and location of the injury or disruption. For a complete discussion of the various risks involved in surgical procedures, see Chapter 146, “Antimicrobial Prophylaxis in Surgery.”

DRUG FACTORS

Pharmacokinetic and Pharmacodynamic Considerations

Integration of both pharmacokinetic and pharmacodynamic properties of an agent is important when choosing antimicrobial therapy to ensure efficacy and to prevent resistance.[36] Early researchers relied solely on pharmacokinetic properties such as the area under the (drug concentration) curve (AUC), maximum observed concentration (peak), and drug half-life to optimize therapy. Pharmacodynamics is the study of the relationship between drug concentration and the effects on the microorganism. There is an important relationship between both pharmacokinetic and microbiologic parameters that has resulted in measurements such as AUC:minimal inhibitory concentration (MIC) ratio, peak:MIC ratio, and time (*T*) the concentration is above MIC (*T*> MIC).[37-41]

Aminoglycosides exhibit concentration-dependent bactericidal effects. An example of the integration of pharmacokinetics and microbiologic activity is the use of high-dose, once-daily aminoglycosides. For these regimens, the drug is given as a single large daily dose to maximize the peak:MIC ratio. Aminoglycosides also possess a post-antibiotic effect (persistent suppression of organism growth after concentrations decrease below the MIC) that contribute to the success of high-dose, once-daily administration. Fluoroquinolones exhibit concentration-dependent killing activity, but optimal killing is characterized by the AUC:MIC ratio.

β-Lactams display time-dependent bactericidal effects. Killing activity is enhanced only marginally if drug concentration exceeds the MIC. Therefore, the important pharmacodynamic relationship for these antimicrobials is the duration that drug concentrations exceed the MIC (*T*> MIC). Effective dosing regimens require serum drug concentrations to exceed the MIC for at least 40% to 60% of the dosing interval. *In vitro*, *in vivo* animal, and human clinical trials have demonstrated improved pharmacodynamic attainment and clinical efficacy with continuous or prolonged infusions of β-lactams.[37] A detailed discussion on antimicrobial pharmacokinetics–pharmacodynamics is beyond the scope of this chapter. However, excellent sources of information on this topic are available.[36,42,43]

Tissue Penetration

The importance of tissue penetration varies with site of infection. Some of the difficulties in interpreting data include a lack of correlation with clinical outcomes and poor understanding of whether the antimicrobial agents are present in a biologically active form. An example of the former problem is the recognized efficacy of drugs with low biliary fluid concentrations in the treatment of cholecystitis, cholangitis, or both and the absence of the enhanced efficacy of drugs whose primary route of elimination is biliary excretion of active drug. An example of the latter difficulty is with penetration to deep infections, such as abscesses, where various factors such as acid pH, WBC products, and various enzymes can inactivate even high concentrations of certain drugs. The CNS is one body site where antimicrobial penetration is relatively well defined, and correlations with clinical outcomes are established.[6,11,44] Cerebrospinal fluid (CSF) concentrations of antimicrobial agents necessary to cure bacterial meningitis have been defined, and drugs that do not reach significant concentrations in the CSF should be either avoided or instilled directly, if feasible. Caution must be exercised when selecting an antimicrobial agent for clinical use on the basis of tissue or fluid penetration. Body fluids where drug concentration data are clinically relevant include CSF, urine, ocular, synovial fluid, and peritoneal fluid. More attention should be paid to clinical efficacy, antimicrobial spectrum, and toxicity than to comparative data on penetration into a given body site.

The proper route of administration for an antimicrobial depends on the site of infection. Parenteral therapy is warranted when patients are being treated for febrile neutropenia or deep-seated infections such as meningitis, endocarditis, and osteomyelitis. Severe pneumonia often is treated initially with IV antibiotics and switched to oral therapy as clinical improvement is evident.[5,22,45] Patients treated in the ambulatory setting for bacterial upper respiratory tract infections (eg, pharyngitis, bronchitis, sinusitis, and otitis media), lower respiratory tract infections, skin and soft-tissue infections, uncomplicated urinary tract infections, and selected sexually transmitted diseases can usually receive oral therapy.

Drug Toxicity

It is incumbent on health professionals to avoid toxic drugs whenever possible. Antibiotics associated with CNS toxicities, usually when not dose-adjusted for renal function, include penicillins, cephalosporins, quinolones, and imipenem. Hematologic toxicities generally are manifested with prolonged use of β-lactam antimicrobials, vancomycin, or sulfamethoxazole/trimethoprim. Reversible nephrotoxicity classically is associated with aminoglycosides and vancomycin. Irreversible ototoxicity can occur with aminoglycosides. In the outpatient setting, patients must be counseled regarding photosensitivity with azithromycin, quinolones, tetracyclines, pyrazinamide, and sulfamethoxazole/trimethoprim. Lastly, all antibiotics have been implicated in causing diarrhea and colitis secondary to *Clostridium difficile* (see Chapter 136, “Gastrointestinal Infections and Enterotoxigenic Poisonings”).[46] List of potential antibiotic adverse drug reactions is provided in Table 127-3.

TABLE 127-3

Antimicrobial Adverse Drug Reactions

Antimicrobial Class	Adverse Drug Reaction	Monitoring Parameters	Comments

Penicillins	Rash, N/V/D, hypersensitivity reactions including anaphylaxis, LFT elevations, interstitial nephritis, cytopenias, hemorrhagic cystitis, *C. difficile* colitis	• Hypersensitivity reactions (eg, bronchospasm, anaphylaxis). • CBC with differential • Renal function • Hepatic function	Immediate IgE-mediated anaphylaxis incidence is <0.05%.
Cephalosporins	Rash, N/V/D, hypersensitivity reactions including anaphylaxis, LFT elevations, interstitial nephritis, cytopenias, Coomb’s positive hemolytic anemia, *C. difficile* colitis	• Hypersensitivity reactions (eg, bronchospasm, anaphylaxis). • CBC with differential • Renal function • Hepatic function	
Carbapenems	Rash, N/V/D, hypersensitivity reactions including anaphylaxis, LFT elevations, interstitial nephritis, cytopenias, eosinophilia, *C. difficile* colitis	• Hypersensitivity reactions (eg, bronchospasm, anaphylaxis). • CBC with differential • Renal function • Hepatic function	Clinically significant cross-sensitivity reactions in penicillin-allergic patients reported to be as low as 1%. Incidence of seizures more frequent in patients who are elderly, have history of seizure disorders, or who have renal dysfunction.
Monobactams	Rash, diarrhea, nausea, LFT elevations, *C. difficile* colitis, thrombocytopenia	• CBC with differential • Renal function • Hepatic function	May be used in patients with anaphylactic penicillin allergy. *Note:* isolated cross-reactivity has been described in ceftazidime-allergic patients due to a shared R-side chain.
Aminoglycosides	Tubular necrosis and renal failure (reversible), vestibular and cochlear toxicity, anemia, hypersensitivity	• Renal function (daily) • SDC • Obtain regular audiology exams in patients with prolonged or cumulative exposure to aminoglycosides	Nephrotoxicity is more common in patients with the following risk factors: elderly, history of renal dysfunction, concomitant administration of nephrotoxic drugs, and prolonged duration of therapy. Ototoxicity can be irreversible.
Glycopeptides	Red man syndrome, phlebitis, renal dysfunction, neutropenia, leukopenia, eosinophilia,	• Renal function • SDC	Red man syndrome is associated with rapid infusion and nonspecific histamine release;

	thrombocytopenia, drug fever	- CBC with differential if on prolonged therapy	prolonging vancomycin infusion and pre-medicating with antihistamines often mitigates occurrence.
Lipopeptides	Elevations in serum creatinine phosphokinase (CPK) levels, rhabdomyolysis, eosinophilic pneumonia.	- Renal function - CPK at baseline and weekly (or more frequently in patients with prior or concomitant statin, renal dysfunction, or patients with baseline elevations in CPK)	Daptomycin doses should be held in the setting of: (1) CPK elevation >5× the upper limit of normal (ULN) in patients who have symptoms of rhabdomyolysis or (2) CPK elevation >10× the ULN in patients who are asymptomatic. Daptomycin may be restarted if CPK level returns to baseline.
Oxazolidinones	Myelosuppression (thrombocytopenia, leukopenia, and anemia), peripheral neuropathy, optic neuropathy, lactic acidosis, diarrhea, nausea, serotonin syndrome	- Monitor for signs and symptoms of serotonin syndrome in patients receiving concomitant serotonergic agents - CBC with differential - For prolonged therapy, monitor visual acuity	Myelosuppression is reversible and associated with treatment duration >2 weeks.
Tetracyclines	GI upset, N/V/D, hepatotoxicity, esophageal ulcerations, photosensitivity, azotemia, visual disturbances, vertigo, hyperpigmentation, hemolytic anemia, pseudotumor cerebri, pancreatitis, *C. difficile* colitis	- CBC with differential - Renal function - Hepatic function	Vestibular symptoms more frequent in women than in men. Avoid use during pregnancy. The American Academy of Pediatrics (AAP) provides guidance on utilization of doxycycline in pediatrics: doxycycline may be used ***without regard to patient age*** for treatment durations ≤21 days.
Chloramphenicol	Myelosuppression, aplastic anemia, “gray baby syndrome,” optic neuritis, peripheral neuropathy, digital paresthesias, GI upset, *C. difficile* colitis, hypersensitivity reactions	- CBC with differential (baseline and daily) - Renal function - Hepatic function - SDC (particularly in children and in patients with hepatic or renal	Bone marrow suppression associated with doses >4 g/day. Use has fallen out of favor due to significant toxicities.

		insufficiency)	
Rifamycines	Red discoloration of urine, tears, contact lens, sweat, hepatotoxicity, GI upset, flu-like syndrome, hypersensitivity, thrombocytopenia, leukopenia, drug fever, interstitial nephritis	• CBC with differential (baseline and daily) • Renal function • Hepatic function (LFTs, bilirubin)	Increased potential for hepatitis with concomitant hepatotoxic drugs (ie, TB drugs).
Macrolides/azalide	GI intolerance, diarrhea, prolonged QTc, cholestatic hepatitis, reversible ototoxicity, torsade de pointes, rash, hypothermia, exacerbation of myasthenia gravis	• Hepatic function in high-risk patients • ECG (baseline and periodically if on multiple QTc-prolonging agents or if prolonged QTc at baseline)	
Clindamycin	Diarrhea, *C. difficile* colitis, nausea, vomiting, generalized rash, hypersensitivity	• Signs/symptoms of *C. difficile* • Hepatic function (if prolonged therapy)	
Fluoroquinolones	GI intolerance, headache, malaise, insomnia, dizziness, photosensitivity, QTc prolongation, tendon rupture, peripheral neuropathy, crystalluria, seizure, interstitial nephritis, Stevens-Johnson syndrome, allergic pneumonitis, *C. difficile* colitis	• Renal function • Signs and symptoms of encephalopathic changes (eg, confusion, hallucinations, and tremor)	Tendon rupture more frequently seen in the elderly and kidney, heart, and lung transplant recipients, and with concurrent use of corticosteroids
Polymyxins	Nephrotoxicity, neurotoxicity (paresthesia, vertigo, ataxia, blur red vision, slurred speech), neuromuscular blockade, bronchospasms (when administered via inhalation)	• CBC with differential (baseline and daily) • Renal function (baseline and daily) • Signs of neurotoxicity (eg, peripheral paresthesias, blurred vision, apnea, muscle weakness)	Nephrotoxicity is dose-dependent.

Sulfonamides and trimethoprim	GI intolerance, rash, hyperkalemia, bone marrow suppression (eg, anemia with folate deficiency, thrombocytopenia, and leukopenia), serum sickness, hepatitis, photosensitivity, crystalluria with azotemia, urolithiasis, methemoglobinemia, Stevens-Johnson syndrome, toxic epidermal necrolysis, pancreatitis, interstitial nephritis	• Hypersensitivity reactions (eg, bronchospasm, anaphylaxis) and rash • CBC with differential • Renal function • Hepatic function • Serum potassium	HIV-infected patients are at increased risk for developing adverse drug reactions. Methemoglobinemia due to severe G6PD deficiency.
Metronidazole	N/V/D, headache, metallic taste, dark urine, peripheral neuropathy, disulfiram reactions with alcohol, insomnia, stomatitis, dysarthria	• CBC with differential (baseline and periodically during prolonged therapy) • Hepatic function • Signs of neurotoxicity	Peripheral neuropathy is reversible and associated with prolonged treatment.

CBC, complete blood count; CPK, creatine phosphokinase; LFT, liver function test; SDC, serum drug concentrations; TB, tuberculosis.

Aside from consideration of drug toxicity, some antimicrobial use requires more intensive risk–benefit analysis. An example of this is the decision to use isoniazid for treatment of latent tuberculosis. Because the hepatotoxicity of isoniazid increases in frequency with age, older persons (greater than 45 years of age) who have latent tuberculosis must have additional risk factors for tuberculosis to balance the potential toxic effects. These include immunosuppression, or immunocompromising conditions, incuding HIV. Older patients without additional risk factors are more likely to suffer toxicity from isoniazid than derive benefit from its use.

COMBINATION ANTIMICROBIAL THERAPY

⑥ In selecting a drug regimen for a given patient, consideration must be given to the necessity of using more than one drug empirically. Inappropriate or inadequate antimicrobial therapy has been associated with increased morbidity and mortality.[47] Combinations of antimicrobials generally are used to broaden the spectrum of coverage for empirical therapy, achieve synergistic activity against the infecting organism, and mitigate the emergence of resistance.[48,49]

Broadening the Spectrum of Coverage

Increasing the coverage of antimicrobial therapy generally is necessary in two scenarios. The first scenario is in mixed infections where multiple organisms are likely to be present. This is the case in intra-abdominal and female pelvic infections, in which a variety of aerobic and anaerobic bacteria can produce disease.[50] Traditionally, a combination of a drug active against aerobic gram-negative bacilli (such as an aminoglycoside) and a drug active against anaerobic bacteria (such as metronidazole) is selected. Options for monotherapy which possess good activity against both of these types of organisms, include the β-lactam/β-lactamase inhibitor combinations and carbapenems. The second scenario is for critically ill patients with presumed healthcare-associated infections in which an increased spectrum of activity is desirable.[45] Healthcare-associated infections are frequently caused by multi-drug resistant pathogens; combination therapy is often used in this setting to ensure that at least one of the antimicrobials will be active against the pathogen(s).

Synergism

The achievement of synergistic antimicrobial activity is advantageous for some serious bacterial infections. Laboratory tests to identify synergy between antibiotic combinations are described in Chapter e126. Traditionally, combinations of aminoglycosides and β-lactams have been used because these drugs together generally act synergistically against a wide variety of bacteria. However, the data supporting superior efficacy of synergistic over nonsynergistic combinations are weak. At best, synergistic combinations produce better results in infections caused by *Enterococcus* species.[42–44]

The most obvious example of the use of synergy is the treatment of enterococcal endocarditis. The causative organism is usually only inhibited by penicillins, but it is killed rapidly by the addition of gentamicin or ceftriaxone to a penicillin. The need for bactericidal activity in the treatment of endocarditis underscores the need for these synergistic combinations.[9,10]

Preventing Resistance

The use of antimicrobial combinations to prevent the emergence of resistance is applied widely but not often realized. The only circumstance where this has been clearly effective is in the treatment of tuberculosis. The prevalence of resistance to a first-line drug such as isoniazid or rifampin in a population of organisms may be as high as 1 in 10^6 to 10^8. Because the bacterial load in a patient with active tuberculosis often exceeds this, two drugs are given to reduce the likelihood of encountering resistance to less than 1 in 10. There is ample evidence from *in vitro* data and experimental bacterial infections that combinations of drugs with different mechanisms are effective in the prevention of the emergence of resistance.

Disadvantages of Combination Therapy

Although there are potentially beneficial effects from combining drugs, there also are potential disadvantages, including increased cost, greater risk of drug toxicity, and superinfection with even more resistant bacteria.[9,51]The combination of two or more antibiotics can result in antagonistic effects. For example, the effect of antagonism may be evident when one drug induces β-lactamase production and another drug is β-lactamase unstable.

MONITORING THERAPEUTIC RESPONSE

⑦ After antimicrobial therapy has been instituted, the patient must be monitored carefully for a therapeutic response. Culture and sensitivity reports from specimens sent to the microbiology laboratory must be reviewed and the therapy changed accordingly. Use of agents with the narrowest spectrum of activity against identified pathogens is recommended. If anaerobes are suspected, even if they are not identified, anti-anaerobic therapy should be continued.

Patient monitoring should include many of the same parameters used to diagnose the infection. The WBC count and temperature should start to normalize. Physical complaints from the patient also should diminish (ie, decreased pain, shortness of breath, cough, or sputum production). Appetite should improve. However, radiologic improvement can lag behind clinical improvement.

Determinations of serum (or other fluid) levels of antimicrobials can be useful in ensuring outcome, preventing toxicity, or both. Vancomycin, aminoglycosides, and voriconazole are examples of antimicrobials that require routine monitoring of serum concentrations. Achievement of adequate aminoglycoside concentrations within the first few days of therapy of gram-negative infection has been correlated with better therapeutic outcome.[52]

Changes in the volume of distribution can have a significant impact on the efficacy and safety of therapy. An unexpectedly low volume of distribution (such as in the dehydrated patient) will result in higher, potentially toxic drug concentrations, whereas a larger-than-expected volume of distribution (such as in patients with edema or ascites) will result in low, potentially subtherapeutic concentrations. The most effective methods use measured serum concentrations of the drugs rather than estimations from renal function tests to assess true drug clearance from the body.

⑧ As patients improve clinically, the route of administration should be reevaluated. Transitioning therapy from parenteral to oral (step-downtherapy) has become an accepted practice for many infections.[5,22] Criteria that should be present to justify a switch to oral therapy include (a) overall clinical improvement, (b) lack of fever for 8 to 24 hours, (c) decreased WBC count, and (d) a functioning GI tract. Drugs that exhibit excellent oral bioavailability when compared with IV formulations include fluoroquinolones, clindamycin, doxycycline, metronidazole, linezolid, and trimethoprim–

sulfamethoxazole.

FAILURE OF ANTIMICROBIAL THERAPY

⑨ A variety of factors may be responsible for an apparent lack of response to therapy. Patients who fail to respond over 2 to 3 days require a thorough reevaluation. It is possible that the disease is not infectious or is not bacterial in origin, or there is an undetected pathogen in a polymicrobial infection. Other factors include those directly related to drug selection, the host, or the pathogen. Laboratory error in identification, susceptibility testing, or both (presence of inoculum effect or resistant subpopulations) is a rare cause of antimicrobial failure.

Failures Caused by Drug Selection

Factors related directly to the drug selection include an inappropriate drug selection, dosage, or route of administration. Malabsorption of a drug product because of GI disease (such as a short-bowel syndrome) or a drug interaction (such as complexation of fluoroquinolones with multivalent cations resulting in reduced absorption) can lead to potentially subtherapeutic serum concentrations. Accelerated drug elimination is also possible. This can occur in patients with cystic fibrosis or during pregnancy, when more rapid clearance or larger volumes of distribution can result in low serum concentrations, particularly for aminoglycosides. A common cause of failure of therapy is poor penetration into the site of infection. This is especially true for sites such as the CNS, eye, and prostate gland. Drug failure also can result from drugs that are highly protein bound or that are chemically inactivated at the site of infection.

Failures Caused by Host Factors

Host defenses must be considered when evaluating a patient who is not responding to antimicrobial therapy. Patients who are immunosuppressed (eg, granulocytopenia from chemotherapy or AIDS) may respond poorly to therapy because their defenses are inadequate to eradicate the infection despite seemingly adequate drug regimens. A good example is the poor response of infection in granulocytopenic patients that is seen when their WBC counts remain low during therapy. This contrasts with a much better response when granulocyte counts increase during therapy. Other host factors are related to the need for surgical drainage of abscesses or removal of foreign bodies, necrotic tissue, or both. If these situations are not corrected, they result in persistent infection and, occasionally, bacteremia despite adequate antimicrobial therapy.

Failures Caused by Microorganisms

There are two types of resistance: intrinsic and acquired. Intrinsic is when the antimicrobial agent never had activity against the bacterial species. For example, gram-negative bacteria are naturally resistant to vancomycin because the drug cannot penetrate the outer membrane of gram-negative bacteria. Acquired resistance is when the antimicrobial agent was originally active against the bacterial species but the genetic makeup of the bacteria has changed so the drug can no longer be effective.[53] The strategies used by bacteria to develop acquired resistance are primarily classified into three general mechanisms of resistance: (a) alteration in the target site, (b) changes in membrane permeability (eg, upregulation of efflux pumps, porin channel alterations), and (c) enzymatic inactivation. Bacteria can use one or more of these mechanisms against a specific antibiotic or antibiotic class. Furthermore, a single mechanism of resistance can result in resistance to multiple related or unrelated classes of antibiotics.

Enzymaticin activation through production of β-lactamases can be either plasmid or chromosomally mediated. In addition, the expression of β-lactamases can be induced or constitutive. There are now multiple types and classes of β-lactamases identified, which is beyond the scope of this chapter. However, there are several outstanding publications discussing all of the different types of β-lactamases.[4,54-56] The increase in resistance among bacteria is believed to be a result of continued overuse of antimicrobials in the community, as well as in hospitals, and the increasing prevalence of immunosuppressed patients receiving long-term suppressive antimicrobials for the prevention of infections. These resistance patterns are regionally variable, and susceptibility patterns in the community (or hospital) should be monitored closely to promote judicious antimicrobial selection.[57]

Enterococci have been isolated with multiple resistance patterns and may be resistant to β-lactams (by virtue of β-lactamase production, altered penicillin-binding proteins, or both), vancomycin (via alterations in peptidoglycan synthesis), and aminoglycosides (via enzymatic degradation). *Streptococcus pneumoniae* tends to be highly susceptible to penicillin, vancomycin, levofloxacin, moxifloxacin, and third-generation parenteral cephalosporins. However, resistance to penicillin, certain cephalosporins (including oral third-generation cephalosporins), and macrolides has become increasingly more common. Newer antimicrobial agents such as linezolid and ceftaroline have demonstrated increased activity against penicillin and cephalosporin-resistant *S. pneumoniae.*

Treatment of an infection caused by AmpC β-lactamase producing organisms (eg, *Enterobacter* sp., *Citrobacter* sp., *Serratia marcescens*, indole-positive Proteae, *Acinetobacter* sp., or *Pseudomonas aeruginosa*) with any penicillin, cephalosporin (with the exception of cefepime), or aztreonam is strongly discouraged. Although such therapy may produce an initial clinical response by eradicating some susceptible bacteria in the population, patients will likely experience treatment failure within a few days as the highly resistant AmpC-producing subpopulations have a selective advantage and are uninhibited by these agents. AmpC β-lactamase producing organisms usually retain susceptibility to cefepime and carbapenems but are resistant to all other β-lactams. Non-β-lactam therapy, including trimethoprim/sulfamethoxazole, aminoglycosides, and fluoroquinolones are additional agents that may be utilized once susceptibilities are known. Host defenses are extremely important in this scenario and debilitated patients with pulmonary infections, abscesses, or osteomyelitis are at high risk for drug failure. In these situations, a combination regimen to prevent the emergence of resistance or the use of carbapenem may be warranted for empirical therapy.

- Patient presenting features (eg, age, allergies, predisposing factors)
- Patient medication history (including timing and duration of previous antibiotic use)
- Patient medical history (including past infection and culture data)
- Patient social history (eg, ethanol or illicit drug use)
- Objective data
    - Blood pressure (BP), heart rate (HR), respiratory rate (RR), temperature, height, weight
    - Labs including complete blood count (CBC) with differential and serum creatinine (SCr)
    - Cultures with susceptibilities from appropriate sites for which infectious process is a concern
    - Objective confirmation of presence of infection

Assess

- Hemodynamic stability (e,. systolic BP <90 mm Hg, HR >90 bpm, O_2 saturation <90% [0.9], Respiratory rate > 20 or $PaCO_2$ <32 mm Hg [4.3 kPa])

- Allergy history (including: agent(s), type of reaction, timing of reaction onset, agent(s) (if utilized) to abort reaction, etc.)
- Antimicrobial history (eg, timing, duration, and agent selection)
- Culture history (eg, prior positive cultures and susceptibilities)
- Presence of risk factors for multi-drug resistant infections (eg, recent broad-spectrum antimicrobial exposure, immunocompromising factors)
- Presence of medications with drug-drug interactions; see Table 127-2

Plan*

- Drug therapy regimen including specific antibiotic(s), dose, route, frequency, and duration
- Monitoring parameters including efficacy (eg, fever curve, complete blood count with differential) and safety (eg, nephrotoxicity, hypersensitivity reactions, CPK elevation); see Table 127-3
- Patient education (eg, purpose of therapy, medication administration, drug-drug interactions, and adverse effects); see Tables 123-2 and 123-3
- Monitoring for resolving signs and symptoms of infection and finalized culture results/susceptibilities
- Therapeutic drug monitoring based on pharmacokinetic/pharmacodynamic properties of agent (eg, AUC:MIC, Peak:MIC, trough concentrations) as appropriate
- Schedule follow-up as necessary

Implement*

- Provide patient education regarding all elements of treatment plan
- Schedule follow-up for laboratory monitoring and physical assessment as appropriate

Follow-up: Monitor and Evaluate

- Resolution of signs and symptoms of infection (eg, fever, erythema, leukocytosis, etc.)
- Presence of adverse effects (eg, nephrotoxicity, hypersensitivity reactions, CPK elevation); see Table 127-3
- Therapeutic drug monitoring based on pharmacokinetic/pharmacodynamic properties of agent (eg, AUC:MIC, Peak:MIC, trough concentrations)

**Collaborate with patient, caregivers, and other healthcare professionals.*

⑩ The importance of the selection and continuation of appropriate antimicrobial therapy in acute care hospitals are part of a wide movement that is referred to as "antimicrobial stewardship." Antimicrobial stewardship programs are aimed at optimizing antimicrobial selection, dosing, route, and duration of therapy to maximize clinical cure or prevention of infection while limiting the unintended consequences, such as the emergence of resistance, adverse drug events, and cost. Many institutions have developed an antibiotic stewardship program. The team is generally a multidisciplinary group including representation from microbiology, infection control, administration, information technology, pharmacy including infectious disease-trained clinical pharmacists, and physicians from several disciplines, including infectious disease. Components of antimicrobial stewardship activities include formulary restriction, prospective audit and feedback of antimicrobial prescriptions to clinicians, education, use of clinical order sets and guidelines, de-escalation of therapy, and intravenous to oral antimicrobial conversion.[58,59]

Antibiotic Formulary

One of the main roles of an antimicrobial stewardship team is to decide which antibiotics to include on their formularies. The decision to have a formulary remains controversial; however, restricting choices does encourage familiarity with a core of antibiotics for residents and attending physicians. Open formularies allow the empirical use of any commercially available antibiotics, with recommended guidelines for changes when culture and sensitivity results are finalized. The implementation of the guidelines and restrictions requires the cooperation of the entire medical staff. Education is vital to the success of the antibiotic formulary.

Attention must be paid to the literature on antimicrobials to assist in the selection of therapy. Evidence-based practice guidelines from the Infectious Diseases Society of America can aid clinicians to direct appropriate therapy for specific infectious disease syndromes. In addition, the results from prospective, controlled, randomized clinical trials should be evaluated whenever possible when considering appropriate antimicrobial therapy. Results from prelicensing open trials offer only limited information that can be useful in this regard because patients in these trials generally are not seriously ill and are not infected with multiple resistant bacteria. Other confounding factors found in most clinical situations are excluded by virtue of the study design. Therefore, comparative data in more seriously ill patients are essential for the appropriate application of new agents.

Post-marketing trials are also important because results can demonstrate superiority of one regimen over another, as it relates to efficacy, safety, or cost-effectiveness. Appropriate antimicrobial therapy can change as new organisms are discovered, susceptibility patterns change, new drugs become available, and new clinical trial results are published. Classical thinking in the treatment of infectious diseases will continue to change and evolve to maintain antimicrobial efficacy. Optimal use of modern antimicrobials is just beginning to be defined.

ABBREVIATIONS

AIDS	acquired immunodeficiency syndrome
AST	antimicrobial susceptibility testing
AUC	area under the curve
CSF	cerebrospinal fluid
ESBL	extended-spectrum β-lactamase
HA-MRSA	hospital-acquired methicillin-resistant *Staphylococcus aureus*
IL-1	interleukin 1
MIC	minimal inhibitory concentration
PBP	penicillin-binding protein
PMN	polymorphonuclear
WBC	white blood cell

APPENDIX 127-1: DRUG(S) OF CHOICE, *ALTERNATIVE(S)*

GRAM-POSITIVE COCCI		
Organism	**Drug(s) of Choice**	***Alternatives***
Enterococcus faecalis Serious Infections	Penicillin G *OR* ampicillin + gentamicin *OR* ceftriaxone	*Vancomycin + gentamicin, daptomycin, linezolid*
Enterococcus faecalis Urinary tract infection	Ampicillin, amoxicillin	*Fosfomycin, nitrofurantoin*
Enterococcus faecium *Recommend consultation with ID specialist*	Linezolid, daptomycin	*Eravacycline, omadacycline*
Methicillin-susceptible *Staphylococcus aureus* (MSSA)	Nafcillin, oxacillin, cefazolin	*Daptomycin, trimethoprim/sulfamethoxazole, clindamycin, BL/BLI*
Methicillin-resistant *Staphylococcus aureus* (MRSA) Serious infections	Vancomycin, daptomycin	*Linezolid, ceftaroline*
Methicillin-resistant *Staphylococcus aureus* (MRSA) SSTIs, CAP	Doxycycline, trimethoprim/sulfamethoxazole	*Clindamycin, linezolid, oritivancin, tedizolid, telavancin, dalbavancin*
Group A *Streptococcus* (*S. pyogenes*)	Penicillin G ± clindamycin *OR* linezolid[c]	*Erythromycin, azithromycin, clarithromycin*
Group B *Streptococcus* (*S. agalactiae)*	Penicillin G, ampicillin, amoxicillin	*Cephalexin, clindamycin, vancomycin, azithromycin*
Group C, F, G *Streptococcus*	Penicillin G ± gentamicin, ceftriaxone, vancomycin	*Daptomycin, clindamycin, cefazolin*
Viridans group *Streptococcus*	Penicillin G, ceftriaxone, vancomycin	*Doxycycline, trimethoprim/sulfamethoxazole*
Penicillin-susceptible *Streptococcus pneumoniae*	Penicillin G, ampicillin, amoxicillin	*Ceftriaxone, doxycycline*
Penicillin-resistant *Streptococcus pneumoniae*	Ceftriaxone, vancomycin	*Levofloxacin, moxifloxacin, vancomycin, linezolid, ceftaroline*

GRAM-NEGATIVE COCCI		
Organism	Drug(s) of Choice	*Alternatives*
Moraxella catarrhalis	Ampicillin/sulbactam, amoxicillin/clavulanate	*Trimethoprim/sulfamethoxazole, doxycycline, azithromycin, ceftriaxone*
Neisseria gonorrhoeae	Ceftriaxone	*Gentamicin + azithromycin*
Neisseria meningitides	Penicillin G, ceftriaxone	*Moxifloxacin, ampicillin*

GRAM-POSITIVE BACILLI		
Organism	Drug(s) of Choice	*Alternatives*
Clostridium perfringes	Penicillin + metronidazole +linezolid *OR* clindamycin	*Piperacillin/tazobactam OR meropenem OR imipenem/cilastatin + linezolid OR clindamycin*
Clostridioides difficile (formerly *Clostridium difficile*)	PO vancomycin, fidaxomicin	*Metronidazole*

GRAM-NEGATIVE BACILLI		
Organism	Drug(s) of Choice	*Alternatives*
Acinetobacter spp.	Cefepime, meropenem, imipenem/cilastatin	*Ampicillin/sulbactam, amikacin, fluoroquinolone, minocycline, piperacillin/tazobactam, tigecycline, trimethoprim/sulfamethoxazole*
Bacteroides spp.	Metronidazole	*Piperacillin/tazobactam, meropenem, imipenem, cefoxitin*
Enterobacter spp.	Cefepime, meropenem, imipenem/cilastatin	*Trimethoprim/sulfamethoxazole, amikacin, piperacillin/tazobactam, fluoroquinolone, minocycline, tigecycline*
Escherichia coli	Ceftriaxone	*Cefepime, BL/BLI, fluoroquinolone, trimethoprim/sulfamethoxazole, cephalexin, nitrofurantoin* (cystitis), *meropenem*
Haemophilus influenzae	Ampicillin/sulbactam, ceftriaxone *If* β-lactamase-negative, *may use* ampicillin	*Trimethoprim/sulfamethoxazole, azithromycin, fluoroquinolone, meropenem*
Klebsiella pneumoniae	Ceftriaxone, BL/BLI	*Cefepime, meropenem, fluoroquinolone*
Legionella spp.	Levofloxacin, moxifloxacin, azithromycin	*Erythromycin, ciprofloxacin*
Pasteurella multocida	Ampicillin/sulbactam	*Penicillin G, doxycycline, trimethoprim/sulfamethoxazole*
Proteus mirabilis	Ceftriaxone	*Penicillin G, BL/BLI, cefepime*
Indole-positive *Proteus* (ie, *Providencia spp., Morganella morganii*)	Cefepime, meropenem, imipenem/cilastatin	*Trimethoprim/sulfamethoxazole, amikacin, piperacillin/tazobactam, fluoroquinolone, minocycline, tigecycline*
Pseudomonas aeruginosa	Cefepime, meropenem, amikacin, tobramycin, imipenem/cilastatin, piperacillin/tazobactam	*Ceftazidime, ciprofloxacin, levofloxacin, aztreonam*
Salmonella typhi	Ceftriaxone	*Ciprofloxacin, levofloxacin,* sulfamethoxazole/*trimethoprim, meropenem*
Serratia marcescens	Cefepime, meropenem, imipenem/cilastatin	*Trimethoprim/sulfamethoxazole, amikacin, piperacillin/tazobactam, fluoroquinolone*
Stenotrophomonas maltophilia	Trimethoprim/sulfamethoxazole	*Minocycline, levofloxacin, ceftazidime*

MISCELLANEOUS MICROORGANISMS

Organism	Drug(s) of Choice	*Alternatives*
Chlamydia pneumoniae	Azithromycin, clarithromycin, doxycycline	*Levofloxacin, moxifloxacin*
Mycoplasma pneumoniae	Azithromycin, clarithromycin, doxycycline	*Levofloxacin, moxifloxacin*
Treponema pallidum	Penicillin G	*Ceftriaxone*

MULTI-DRUG RESISTANT (MDR) GRAM-NEGATIVE ORGANISMS

Organism	Drug(s) of Choice	*Alternatives*
Any ESBL-positive *Enterobacterales* Infections outside the urinary tract	Carbapenem	*N/A*
Any ESBL-positive *Enterobacterales* Pyelonephritis	Trimethoprim/sulfamethoxazole	*Carbapenem, levofloxacin, ciprofloxacin*
Any ESBL-positive *Enterobacterales* Cystitis	Nitrofurantoin	*Trimethoprim/sulfamethoxazole, levofloxacin, ciprofloxacin*
Any *Enterobacterales* positive for KPC carbapenemase	Meropenem/vaborbactam, ceftazidime/avibactam, imipenem/cilastatin/relebactam	*Cefiderocol*
Any *Enterobacterales* positive for ametallo-β-lactamase (ie, VIM, NDM, or IMP)	Ceftazidime/avibactam + aztreonam	*Cefiderocol*
Any *Enterobacterales* positive for OXA-48 carbapenemase	Ceftazidime/avibactam	*Cefidericol*
***Pseudomonas aeruginosa* resistant to all routinely tested β-lactams** *Recommendations in chart are assuming in vitro susceptibility*	Ceftolozane/tazobactam	*Ceftazidime/avibactam, imipenem/cilastatin/relebactam, cefiderocol*

ESBL: extended-spectrum β-lactamase; GAS: Group A *Streptococcus*;

[a] Daptomycin does not achieve appreciable CNS concentrations and therefore would not be recommended for treatment of meningitis.

[b] Not appropriate alternatives for treatment of MRSA or MSSA bloodstream infections or CNS infections;

[c] Both clindamycin and linezolid provide anti-toxin activity against GAS and selection of agent dependent upon patient-specific factors;

[d] May consider the addition of rifampin for serious *Legionella* infections,

[e] Fluoroquinolones: ciprofloxacin, levofloxacin, moxifloxacin,

[f] β-Lactam/β-lactamase inhibitor combination: ampicillin–sulbactam, piperacillin–tazobactam, ticarcillin–clavulanate, amoxicillin–clavulanate.

[g] Oral step-down therapy to trimethoprim/sulfamethoxazole, levofloxacin, or ciprofloxacin may be considered after (1) susceptibility to the oral agent is demonstrated, (2) patients are afebrile and hemodynamically stable, (3) appropriate source control is achieved, and (4) there are no issues with intestinal absorption.

[h] Carbapenem: meropenem, imipenem/cilastatin, ertapenem

SELF-ASSESSMENT QUESTIONS

1. Which of the following are true regarding Antimicrobial Stewardship programs?

A. Antimicrobial stewardship programs are aimed at optimizing antimicrobial selection, dosing, route, and duration of therapy to maximize patient outcomes.

B. The main goal of antimicrobial stewardship programs is to minimize all costs to manage all infectious diseases.

C. A successful antimicrobial stewardship program involves primarily the participation of the infection control department.

D. None of the above are true.

2. Important considerations when selecting empiric antimicrobial therapy include which of the following?

A. Prior antimicrobial use

B. Site of infection and the organisms most likely present

C. Prior knowledge of colonization or infections

D. All of the above

3. Which of the following groups of physical examination findings and laboratory values is suggestive of an infection?

A. Temperature 98.9°F (37.2 °C); WBC $11 \times 10^3/\text{mm}^3$ (11×10^9/L); Bands 0%

B. Temperature 98.1°F (36.7 °C); WBC $6.1 \times 10^3/\text{mm}^3$ (6.1×10^9/L); Bands 2%

C. Temperature 96.4°F (35.8 °C); WBC $21 \times 10^3/\text{mm}^3$ (21×10^9/L); Bands 10%

D. All of the above

4. Which of the following statements considering microbiological studies in antimicrobial therapy is false:

A. A delay in obtaining cultures until after antimicrobial therapy is started might result in false-negatives.

B. Ideally two sets of blood cultures should be obtained peripherally from two different sites 1 hour apart.

C. Coagulase-negative staphylococci recovered from blood cultures always warrant antimicrobial treatment.

D. Urine cultures should be evaluated in conjunction with results of the urinalysis to confirm infection.

5. Change from parenteral to oral therapy may be considered based on which of the following factor(s)?

A. Tolerating oral diet

B. Hemodynamically stable

C. Afebrile for 24 hours

D. All of the above

6. Which of the following is a major antibiotic-drug interaction?

A. Rifampin–Warfarin

B. Erythromcyin–Amiodarone

C. Isoniazid–Phenytoin

D. All of the above

7. Which of the following is not an antimicrobial pharmacodynamic parameter?

A. AUC:MIC

B. % *T* above MIC

C. MIC:bioavailability

D. Peak:MIC

8. Which of the following statements regarding synergy and combination antimicrobial therapy is true:

A. The combination of any two antimicrobials will always result in synergistic effects

B. There is strong evidence to support synergistic combinations for the treatment of gram-negative bacilli in all infectious diseases.

C. An example of synergy is the addition of an aminoglycoside to a penicillin in the treatment of enterococcal endocarditis.

D. None of the above.

9. Identify the most appropriate monitoring parameter to assess response to antimicrobial therapy.

A. Re-culture twice daily to ensure adequate microbiological cure

B. Complete blood cell count with differential

C. Serum electrolytes

D. Caloric intake

10. Which of these statements provides the best rationale for the use of combination therapy:

A. Combination therapy broadens spectrum of coverage for empirical therapy.

B. Combination therapy may decrease the occurrence of toxicities.

C. Prolonged combination therapy has been consistently proven to improve outcomes in clinical trials.

D. All of the above.

11. Which of the following group of antimicrobials is known to cause nephrotoxicity?

A. Colistin, tobramycin, rifamycins, tetracycline

B. Chloramphenicol, tobramycin, colistin, vancomycin

C. Ceftriaxone, amikacin, doxycycline, linezolid

D. Vancomycin, moxifloxacin, tobramycin, tetracycline

12. In a patient with liver insufficiency, which of the following medications would warrant dose-adjustment?

A. Vancomycin

B. Cefazolin

C. Metronidazole

D. Ciprofloxacin

13. What scenario may not be associated with poor clinical response to antimicrobial therapy?

A. Inadequate source control

B. Inadequate antimicrobial spectrum

C. Antimicrobial therapy in a neutropenic patient

D. Antimicrobial combination is not concentration dependent

14. A concern of using combination therapy would include:

A. Increase risk for super-infections

B. Increase risk for drug toxicities

C. Possibility of antagonistic effects of combination of 2 or more antibiotics

D. All of the above

15. Activities of an antimicrobial stewardship programs may include which of the following:

A. Antimicrobial utilization reporting

B. Providing education for the appropriate use of antimicrobials

C. Prospective audit and feedback

D. All of the above

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A**. Please see the "Antimicrobial Stewardship Principles" section for more details.

2. **D**. Each of the following considerations are important when selecting empiric antimicrobial therapy. Please see Table 127-1.

3. **C**. Answer choice C represents the grouping of findings most likely suggestive of an infection with a temperature (<96.8°F) and elevated WBC count with an increase in immature neutrophils (bands).

4. **C**. Coagulase-negative staphylococci recovered from blood cultures often represents contamination with colonizing skin flora.

5. **D**. Please see the “Monitoring Therapeutic Response” section.

6. **D**. Please see Table 127-2.

7. **C**. Although bioavailability is important when managing patients with infectious diseases, it is not a consideration when utilizing serum or plasma concentrations of drug to calculate pharmacodynamic parameters.

8. **C**. Answer choice A is incorrect as combination therapy will not always result in synergy, and in fact may at times result in antagonism. See the “Synergism” section for more detailed explanation.

9. **B**. Answer choices C and D are incorrect as caloric intake and serum electrolytes are not utilized to monitor microbiological response. Answer choice A is incorrect as a blood culture should be obtained every 48 hours until culture clearance.

10. **A**. Answer choices B and C are incorrect as combination therapy may increase occurrence of toxicity and has failed to demonstrate improved outcomes in clinical trials.

11. **B**. See Table 127-3 for more detailed information related to nephrotoxicity of antimicrobial therapy.

12. **C**. Metronidazole is the only agent which may require dose adjustment with severe hepatic impairment.

13. **D**. Patients with immunocompromising conditions, scenarios where there is inadequate source control, and antimicrobial therapy considered inadequate for present infection are all risk factors associated with poor clinical response.

14. **D**. Increased occurrence of drug toxicities, antagonistic effects of antibiotics utilized in combination, and risk of super infection are all complications associated with combination therapy.

15. **D**. Antimicrobial stewardship programs may be involved in each of the listed tasks. Please see the “Antimicrobial Stewardship Principles” section for more details.

Chapter 128: Central Nervous System Infections

Delaney E. Hart; Christina Koutsari; Michael A. Wankum; Ramy H. Elshaboury

KEY CONCEPTS

KEY CONCEPTS

①The four most common causative pathogens of acute community-acquired bacterial meningitis in the United States are *Streptococcus pneumoniae*, group B *Streptococcus, Neisseria meningitidis*, and *Haemophilus influenzae* type b, although routine vaccinations are having a dramatic effect on the incidence and distribution of these pathogens.

②In cases of bacterial meningitis, initial findings can include (a) presenting signs and symptoms: fever, headache, nuchal rigidity (the classic triad), Brudzinski's or Kernig's sign, and altered mental status; and (b) abnormal cerebrospinal fluid (CSF) chemistries: elevated white blood cell (WBC) count (>1,000 cells/mm^3 [1.0 × 10^9/L]), elevated protein (>50 mg/dL [500 mg/L]), and decreased glucose levels (<45 mg/dL [2.5 mmol/L]).

③Main microbiologic tests that should be obtained include Gram stain and culture of the CSF and blood. In patients with negative CSF Gram stain and culture, molecular testing such as polymerase chain reaction (PCR) has additive value in the pathogen(s) identification.

④Three primary goals of treatment in meningitis include (a) eradication of infection, (b) amelioration of signs and symptoms, and (c) prevention of the development of neurologic sequelae, such as seizures, deafness, coma, and death.

⑤When selecting antibiotics, the clinician must consider the antibiotic concentration at the site of infection and the spectrum of antibacterial activity. Empirical choices should be based on age, predisposing conditions, vaccination history, comorbidities, and local susceptibility patterns.

(a) Either ceftriaxone or cefotaxime with vancomycin is a reasonable initial choice for empirical coverage of community-acquired meningitis in adult patients. (b) Meningitis due to *Listeria monocytogenes* is more common in infants and elderly. Therefore, ampicillin—with or without gentamicin—should be empirically added to antimicrobial regimens in these age groups.

⑥Empirical coverage with an appropriate antibiotic should be started as soon as possible when clinical suspicion of meningitis exists. If there is a delay in obtaining a lumbar puncture (even 30-60 minutes), or if the patient is to undergo neuroimaging, the first dose of antibiotic(s) should not be withheld.

⑦Antibiotic dosages for the treatment of meningitis should be optimized to ensure adequate CNS therapeutic concentrations.

⑧The duration of antibiotic treatment for acute bacterial meningitis has not been standardized. However, it is generally based on the causative organism and the individual case, and may range from 7 to 21 days.

⑨Close contacts and relatives of the index case should be assessed for appropriate chemoprophylaxis and vaccinations, particularly for *N. meningitidis* and *H. influenzae* meningitis.

⑩Steroid treatment includes dexamethasone of 0.15 mg/kg per dose given four times daily for 2 to 4 days in infants and children with proven or strongly suspected *H. influenzae* type b meningitis. Steroids should be started 10 to 20 minutes prior to, or at least concomitant with, the first dose of antibiotics.

BEYOND THE BOOK

Find the Infectious Diseases Society of America (IDSA) guidelines for the diagnosis and treatment of neurocysticercosis infection. Assume that a male patient who is 90 kg and has normal kidney function requires treatment. Create a treatment regimen with drug, dose (both in mg/kg and in mg), dosing interval, and monitoring parameters for each recommended agent. When are antiparasitic agents used and when are they not given? The purpose of this activity is to enhance your ability to find evidence-based guidelines and apply them to clinical practice.

INTRODUCTION

Central nervous system (CNS) infections are caused by a variety of pathogens, including bacteria, viruses, fungi, and parasites. CNS infections result from hematogenous spread from a primary infection site, seeding from a parameningeal focus, reactivation from a latent site, trauma, neurosurgery, or CNS congenital defects. Newer diagnostic techniques have enabled more rapid and definitive diagnosis, thus reducing the number of unknown "aseptic meningitis" diagnoses and improving targeted therapy. Bacteria resistant to multiple antibiotics present new challenges in the management of CNS infections. This chapter presents the epidemiology, etiology, pathophysiology, therapy, and prophylaxis of common CNS infections.

EPIDEMIOLOGY

The incidence of acute, community-acquired bacterial meningitis is approximately 0.7 to 0.9 per 100,000 persons annually in developed countries, including the United States and Western Europe.[1] In the United States, this corresponded to approximately 4,100 annual cases of acute community-acquired bacterial meningitis, excluding epidemics, between 2003 and 2007 resulting in approximately 500 deaths.[2] In stark contrast, incidence rates of meningitis in the region of sub-Saharan Africa average 10 to 40 cases per 100,000 people per year.[1] This region, also known as the "meningitis belt," is characterized by seasonal and explosive epidemics putting at least 350 million individuals at risk for meningitis annually.[3]

The estimated incidence of brain abscesses is 0.3 to 1.3 per 100,000 people per year but can be considerably higher in high-risk groups, such as patients with HIV/AIDS.[4] The global reported incidence of encephalitis varies according to the population studied, and due to differences in definitions and research methodology. The reported incidence in western settings ranges from 0.7 to 13.8 per 100,000 for all ages: 0.7 to 12.6 per 100,000 adults and 10.5 to 13.8 per 100,000 children. The incidence peaks in the young and the elderly.[5,6] In the United States, there are approximately 20,000 encephalitis-related hospitalizations and 1,400 deaths per year.[7,8]

ETIOLOGY

① *Streptococcus pneumoniae* remains the leading cause of acute community-acquired bacterial meningitis in the United States with an incidence rate of 0.3 per 100,000 people in 2010.[9] *Neisseria meningitidis* and *Haemophilus influenzae* type b (Hib) have also been important causes of acute bacterial meningitis but their incidence has decreased substantially in the past several decades, mainly due to introduction of effective vaccinations. *S. pneumoniae* remains the leading cause of bacterial meningitis, followed by Hib, *N. meningitidis*, and other bacterial, viral, and fungal causes.[10]

Hib was the most commonly identified cause of bacterial meningitis until the introduction of the Hib conjugate vaccine in 1987 (at 18 months of age) and 1991 (at 2 months of age) in the United States. Hib vaccination had a profound population-wide effect on incidence of Hib meningitis, and in 2016 Hib was the least common cause of meningitis.[10] Targeted meningococcal vaccination for high-risk infants, adolescents, and adults have similarly impacted the epidemiology and risk of meningococcal meningitis following the availability of meningococcal vaccines in the United States.[11]

Organisms causing healthcare-associated ventriculitis and meningitis differ markedly from those causing community-acquired bacterial meningitis. The most likely pathogens associated with CSF shunt and drain infections are coagulase-negative staphylococci, *Staphylococcus aureus, Propionibacterium (now Cutibacterium) acnes*, and gram-negative bacilli (including *Escherichia coli*, Enterobacter species, Citrobacter species, Serratia species, and *Pseudomonas aeruginosa*).[12]

Infectious encephalitis is caused by many viruses, bacteria, parasites, and fungi.[5,13,14] Noninfectious processes can also cause encephalitis and, as a result, the etiology remains unknown in 20% or more of encephalitis cases. Viral encephalitis in the United States is often caused by enteroviruses, herpes viruses, and arboviruses.[7,15,16]

ANATOMY AND PHYSIOLOGY OF THE CENTRAL NERVOUS SYSTEM

Meninges

The skull and vertebrae protect the CNS from blunt or penetrating trauma (Fig. 128-1). The brain is suspended in these structures by CSF and is surrounded by the meninges. The meninges are made up of three separate membranes: dura mater, arachnoid, and pia mater.[17] Dura mater, or pachymeninges, lies directly beneath and is adherent to the skull. The other two membranes are referred to collectively as leptomeninges. Pia mater lies directly over brain tissue. Arachnoid, the middle layer, lies between the dura mater and the pia mater. The subarachnoid space, located between the arachnoid and the pia mater, is the conduit for CSF. Meningitis refers to inflammation of the subarachnoid space or spinal fluid, whereas encephalitis is an inflammation of the brain tissue itself. Since infectious microorganisms frequently are an underlying cause of these inflammatory processes, the terms "meningitis," "encephalitis," and "meningoencephalitis" are frequently used to denote an infectious process.[18]

Cerebrospinal Fluid

Approximately 85% of the CSF is produced within the third, fourth, and lateral ventricles by the choroid plexus (Fig. 128-1). CSF volume in the CNS is related to patient age: infants have approximately 40 to 60 mL of CSF, older children have 60 to 100 mL, while adults have 115 to 160 mL. Normally, CSF is produced at the rate of approximately 500 mL/day and flows unidirectionally downward through the spinal cord. The CSF is removed by the arachnoid villi and vertebral venous plexus located in the spinal cord and does not recommunicate with the point of production.[18]

② The CSF normally is clear, with a protein content of less than 50 mg/dL (500 mg/L), a glucose concentration of approximately 50% to 60% of the simultaneous peripheral serum glucose concentration, and a pH of approximately 7.4. Also, it typically contains fewer than 5 WBCs per mm^3 (5×10^6/L), all of which should be lymphocytes (Table 128-1).[3,19] As meninges become inflamed, CSF abnormalities can be used diagnostically as markers of CNS infections.

TABLE 128-1

Mean Values of the Components of Normal and Abnormal Cerebrospinal Fluid

Type	Normal	Bacterial	Viral	Fungal	Tuberculosis
WBC (cells/mm^3 or 10^6/L)	<5 (<30 in newborns)	1,000-5,000	50-1,000	20-500	25-500
Differential[a]	Monocytes	Neutrophils	Lymphocytes	Lymphocytes	Lymphocytes
Protein (mg/dL)	<50 (500 mg/L)	Elevated	Mild elevation	Elevated	Elevated
Glucose (mg/dL)	45-80 (2.5-4.4 mmol/L)	Low	Normal	Low	Low
CSF/blood glucose ratio	50%-60%	Decreased	Normal	Decreased	Decreased

Blood–Brain Barrier/Blood–CSF Barrier

Natural barriers to the exchange of drugs and endogenous compounds among the blood, brain, and CSF are the blood–brain barrier (BBB) and the blood–CSF barrier (BCSFB) Fig. 128-2. The BBB consists of tightly joined capillary endothelial cells. Drug entry into brain tissue is accomplished by direct passage through the capillary endothelial cells and further penetration of the glial cells that envelop the capillary structure.[18] Passage of drugs into the CSF is controlled by the BCSFB. This barrier is created by ependymal cells of the choroid plexus, which function as an active-transport system similar to the renal tubular epithelial cells. The inflammatory process associated with meningitis can also inhibit the active-transport system of the choroid plexus.

PATHOPHYSIOLOGY OF THE CNS INFECTION

The development of bacterial meningitis involves four main processes: (1) mucosal colonization and bacterial invasion of the host and CNS; (2) bacterial replication in the subarachnoid space; (3) pathophysiologic alterations resulting in progressive inflammation; and (4) increased intracranial pressure (ICP) and cerebral edema leading to neuronal damage.[3,20] Many bacteria that cause meningitis initially colonize the mucous membranes of the upper respiratory tract. Immunoglobulins (Ig), such as secretory IgA, are found in high concentrations within nasopharyngeal secretions and work to inhibit bacterial colonization. However, this mucus barrier is deteriorated by IgA proteases secreted by bacteria, which allows bacteria to adhere to the host cell surface receptors.

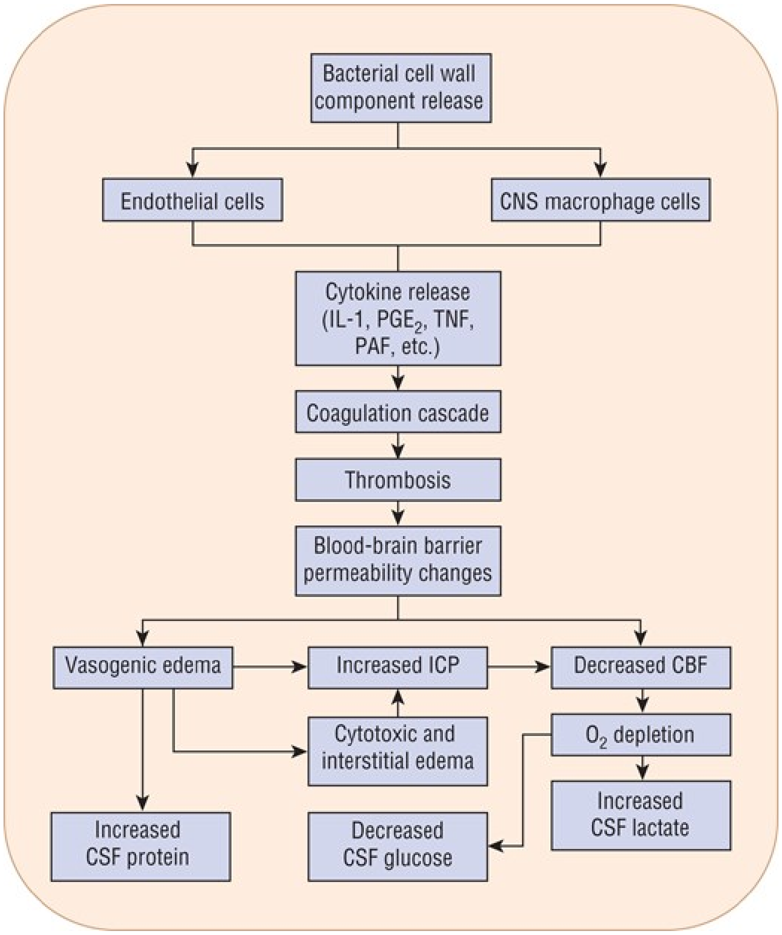
Bacterial pathogens tightly attach to nasopharyngeal epithelial cells and are then phagocytized into the host's bloodstream. Invasion into the bloodstream occurs either transcellularly (passing through the cells) or paracellularly (between cells). After accessing the patient's bloodstream, bacteria must overcome the host's defense mechanisms. Commonly, CNS bacterial pathogens produce an extensive polysaccharide capsule resistant to neutrophil phagocytosis and complement opsonization. Capsular polysaccharides activate the alternate complement pathway, which promotes phagocytosis and clearance of infecting pathogens. Patients unable to activate the alternative complement pathway, such as those with asplenia or sickle cell anemia, are predisposed to bacterial infections caused by encapsulated microorganisms and, therefore, are at increased risk for meningitis. Most cases of acute bacterial meningitis likely occur following bacteremia, but the high incidence of pneumococcal meningitis in patients with sinusitis and otitis media suggests that direct spread to the CNS can also occur.[3]

Although the exact site and mechanism of bacterial invasion into the CNS is unknown, invasion into the subarachnoid space may occur by continuous exposure of the CNS to large bacterial inoculum. Micro-organisms utilize three main mechanisms to directly transit the blood−brain barrier: transcellular route, paracellular route, and lytic mechanism.[21] Host defense mechanisms within the subarachnoid space are inadequate to combat bacterial pathogens. Therefore, bacteria replicate freely within the CSF. Although in most cases of bacterial meningitis the neurological syndrome is caused by the pathogen having invaded into the CNS, some bacteria such as the Shiga toxin-producing *Escherichia coli* (*E. coli*) attack from outside the CNS using toxins.[22]

The effects of meningitis, namely inflammation within the subarachnoid space and the ensuing neurologic damage, are not necessarily a direct result of the pathogens themselves. The neurologic sequelae occur due to the activation of the host's inflammatory pathways, a process induced by the pathogen or its products. Bacterial cell lysis and subsequent death can result in the release of cell-wall components, such as lipopolysaccharide (LPS), lipid A (endotoxin), lipoteichoic acid, teichoic acid, and peptidoglycan, depending on whether the pathogen is gram-positive or gram-negative (Fig. 128-3). These cell-wall components cause capillary endothelial cells and CNS macrophages to release cytokines (interleukin-1 [IL-1] and tumor necrosis factor [TNF]) and other inflammatory mediators (IL-6, IL-8, platelet-activating factor [PAF], nitric oxide, arachidonic acid metabolites [eg, prostaglandin and prostacycline], and macrophage-derived proteins). Proteolytic products and toxic oxygen radicals are released from the capillary endothelium, causing an alteration in the permeability of the BBB. Platelet-activating factor activates the coagulation cascade, and arachidonic acid metabolites stimulate vasodilation. These events propagate other sequential events that can lead to cerebral edema, ICP, CSF pleocytosis, decreased cerebral blood flow, cerebral ischemia, and possibly death.

FIGURE 128-3

Hypothetical schema of pathophysiologic events that occur during bacterial meningitis. (CBF, cerebral blood flow; CSF, cerebrospinal fluid; ICP, intracranial pressure; IL-1, interleukin-1; PAF, platelet-activating factor; PGE$_2$, prostaglandin E$_2$; TNF, tumor necrosis factor.)



Bacterial cell wall component release
Endothelial cells
CNS macrophage cells
Cytokine release (IL-1, PGE$_2$, TNF, PAF, etc.)
Coagulation cascade
Thrombosis
Blood-brain barrier permeability changes
Vasogenic edema
Increased ICP
Decreased CBF
Cytotoxic and interstitial edema
O$_2$ depletion
Increased CSF lactate
Increased CSF protein
Decreased CSF glucose

CLINICAL PRESENTATION AND DIAGNOSIS

Clinical presentation of CNS infections varies with host age, immune status, duration of illness, and the specific pathogen causing the infection.

Signs and Symptoms

② Classic signs and symptoms of acute bacterial meningitis include fever, nuchal rigidity, altered mental status (the classic triad), chills, nausea, vomiting, photophobia, and severe headache. Kernig's and Brudzinski's signs may also be present but are poorly sensitive and frequently absent in children (Figs. 128-4 and 128-5). Additionally, clinical signs and symptoms in young children may include bulging fontanelle, apneas, purpuric rash, irritability, refusal to eat, and convulsions. The classic triad occurs in <50% of adult patients with acute bacterial meningitis.[23] However, up to 95% of patients exhibit at least two of following symptoms: fever, nuchal rigidity, headache, and altered mental status. Purpuric and petechial skin lesions may indicate meningococcal involvement, although lesions may also be present with *H. influenzae* meningitis.[24]

As opposed to acute bacterial meningitis, symptoms of chronic meningitis, defined as 4 weeks of symptoms of meningitis or meningoencephalitis, can be present over weeks and months. Examples include *Mycobacterium tuberculosis* and fungal meningitis (eg, due to Cryptococcus, Histoplasma, or Aspergillus species). Early symptoms of chronic meningitis may include headache, nausea, and decreased memory or comprehension, while later symptoms may include double vision, cranial nerve palsies, unsteady gait, emesis, and confusion.[19]

The clinical manifestations of brain abscess depend on the size and location of the space-occupying lesion. Common symptoms include headache, focal neurologic deficits, motor speech disorder, ataxia, fever, nystagmus, seizures, and vomiting. The clinical course can be indolent or fulminant depending on the virulence of the pathogen.

The classical clinical features of infective encephalitis in adults include fever, abnormal mental status (often with severe headache), nausea, and vomiting. Seizures can also be the initial presenting feature of patients with infectious encephalitic processes affecting the cortex.[5,14] Lastly, ill children cannot often adequately describe symptoms such as headache, whereas infants commonly have nonspecific symptoms similar to those for other acute illnesses including feeding and respiratory difficulties.[13]

Diagnostic Tests

③CSF examination is essential for establishing diagnosis of bacterial meningitis, identifying the pathogen, and performing susceptibility testing. CSF polymorphonuclear pleocytosis, an elevated CSF protein of >50 mg/dL (500 mg/L), and a CSF glucose concentration of <50% of the simultaneously obtained peripheral value suggest bacterial meningitis (Table 128-1).[3,19] However, the values for CSF glucose, protein, and WBC found with bacterial meningitis overlap significantly with those with viral, tuberculous, and fungal meningitis (Table 128-1). Therefore, CSF WBC count and CSF glucose and protein concentrations cannot always distinguish the different etiologies of meningitis. CSF culture is the gold standard for diagnosis of bacterial meningitis and is positive in 80% to 90% of patients with community-acquired bacterial meningitis if the CSF sample is obtained before the start of antibiotics.[24] In addition, Gram stain is a rapid, inexpensive, and accurate method to assess the presence of bacteria in CSF. However, the sensitivity of the Gram stain depends on the causative microorganism, so that its aggregate diagnostic yield is 90% in pneumococcal, 70% to 90% in meningococcal, 50% in *H. influenzae*, and only 25% to 35% in *L. monocytogenes* meningitis.[25]

In patients presenting with new-onset seizures, signs of space-occupying lesions, or moderate-to-severe impairment of consciousness, cranial imaging via magnetic resonance imaging (MRI) or cranial computed tomography (CT) should precede a lumbar puncture. MRI is generally preferred, as it more clearly identifies areas of cerebral edemas and has higher specificity and sensitivity than CT.[26] Neuroimaging or CSF cultures should not delay initiation of appropriate antibiotic therapy as doing so can result in a poor outcome in this disease.

③In patients with suspected CNS bacterial infection, blood cultures are strongly recommended and should be collected before the first dose of antibiotics. Blood cultures identify the causative organism in 50% to 80% of cases, although the yield decreases by 20% if the patient has received antibiotics.[24] CSF viral cultures are insensitive for the diagnosis of viral encephalitis/meningitis. Patients with suspected encephalitis should have a CSF PCR test for HSV1, HSV2, VZV, and enteroviruses, as this will identify ~90% of cases due to known viral pathogens.[27]

Models have been developed in an attempt to predict the likelihood of acute community-acquired bacterial versus viral meningitis. Expert opinions and guidelines have systematically evaluated these models and identified concerns that limit their use in clinical practice.[24,27] Limitations include <100% sensitivity (risk of false-negative results), application limited to age-specific cohorts in which the models were developed, and ability to only differentiate between acute bacterial versus viral meningitis when in clinical practice other causes are also considered.

CSF lactate may be useful in differentiating between bacterial and other types of meningitis.[12,27] In a meta-analysis of 1,881 adult and pediatric patients, CSF lactate had a sensitivity of 93% and a specificity of 96% in differentiating bacterial from aseptic meningitis, when the specimen was collected before antibiotics. However, administration of antibiotics reduced sensitivity to 49%, suggesting that the usefulness of CSF lactate is compromised in patients who have already received antimicrobial therapy.[28] CSF and/or serum procalcitonin (PCT) may be useful markers for bacterial cause in community-acquired and healthcare-associated meningitis.[29,30] However, more studies are needed to confirm the impact of PCT monitoring on clinical outcomes, establish cut-off values, and evaluate cost-effectiveness.

3 Polymerase chain reaction (PCR) techniques can rapidly diagnose CNS infections and may be particularly useful in patients who have received antimicrobial therapy before lumbar puncture, have negative cultures, or when the organism is fastidious or fails to grow in conventional culture.[5,12,27] In addition to individual PCR tests, a multiplex PCR panel can simultaneously and rapidly (within ~1 hour) detect six bacterial, seven viral, and two yeast targets directly from CSF specimens; however, more studies are needed to establish performance in clinical practice.[31] Antimicrobial stewardship programs when combined with rapid diagnostic bloodstream tests have been shown to optimize antimicrobial use, though more data is needed in antimicrobial stewardship initiatives with CNS PCR tests.[32] Routine cultures are necessary for the detection of pathogens not covered by the multiplex PCR panel and for antibiotic susceptibility testing. 16s rRNA molecular testing and next generation sequencing are also emerging as diagnostic tools for CNS infections.[33,34] Ribosomal 16s is part of the 30s ribosomal subunit in bacteria. By identifying species-level 16s sequences, this testing can detect a causative pathogen for patients whose cultures are negative. Due to low positivity, high cost, and slow turnaround time, ribosomal 16s testing should be applied on a case by case basis.[35]

Latex agglutination has little incremental value and is not a recommended routine diagnostic modality for rapid determination of bacterial etiology of meningitis.[12,26,27] More studies are needed to determine whether immunochromatographic antigen testing has incremental value in the diagnosis of bacterial meningitis.

Diagnosis of tuberculous meningitis employs acid-fast stain, culture, and PCR of the CSF. The standard diagnostic tests for fungal meningitis include culture, direct microscopic examination of stained and unstained specimens of CSF, antigen detection of cryptococcal or histoplasma, and antibody assay of serum and/or CSF.

FIGURE 128-4

(A and B) Brudzinski’s neck signs. (B) Hip and knee flexion occurs as a result of flexion of the neck. (C to E) Brudzinski’s leg signs. (C) Patient’s leg is flexed by examiner (*arrow*). (D) The contralateral leg begins to flex—identical contralateral sign (*arrows*). (E) The contralateral leg now begins to extend spontaneously, resembling a little kick (*arrows*).

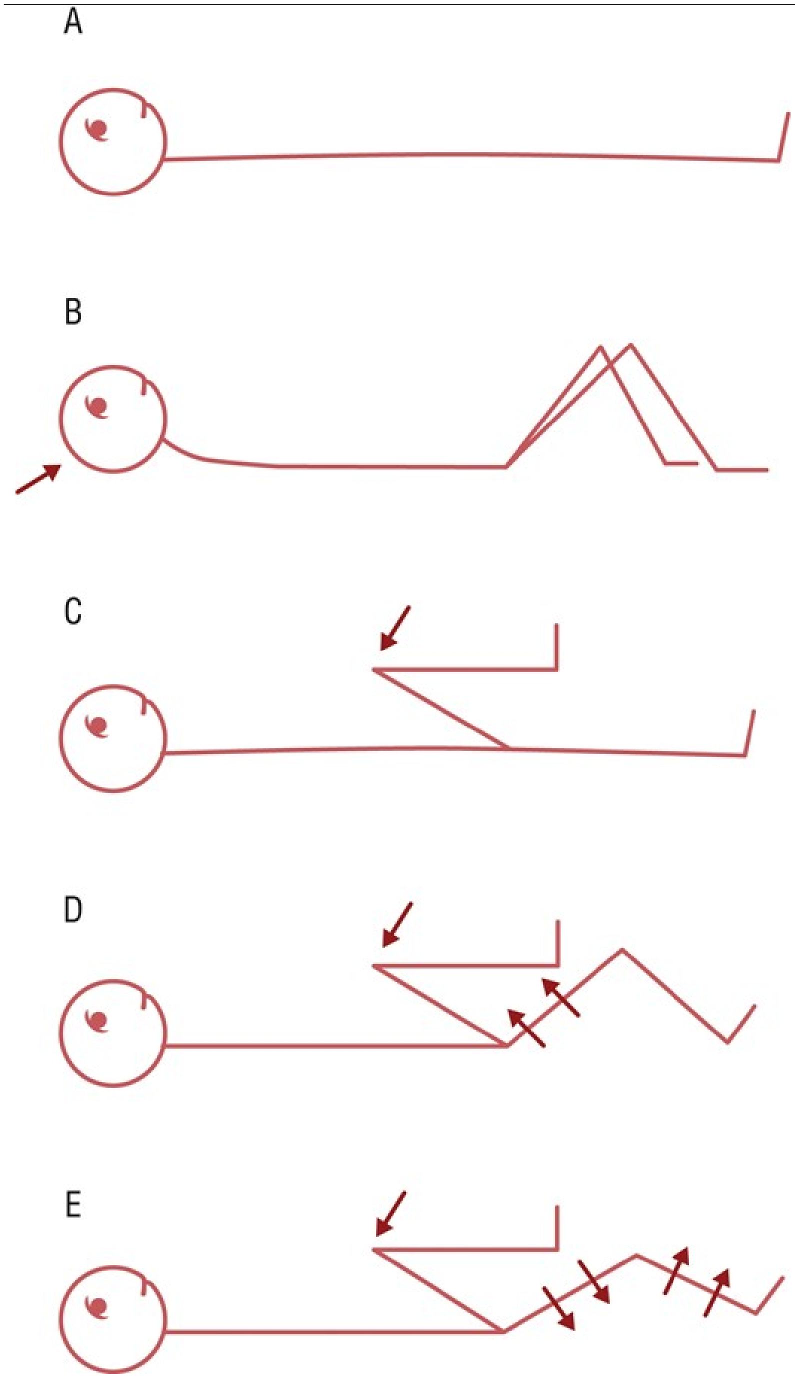


FIGURE 128-5

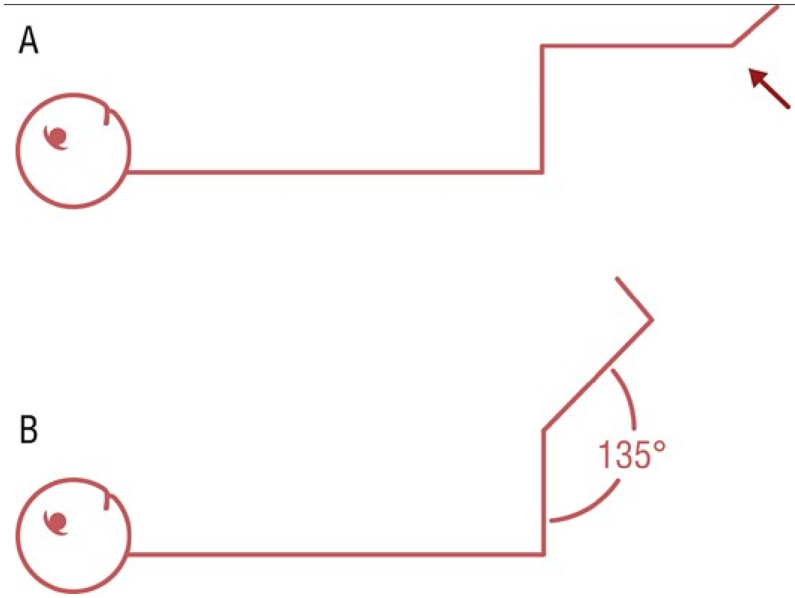
Kernig's sign. (A) Knees are raised to form a 90-degree angle relative to the trunk, and the examiner attempts to extend the knees. (B) Once the knee angle reaches approximately 135 degrees, contracture or extensor spasm occurs.



TREATMENT

Desired Outcome

④Goals for the treatment of CNS infections should include prompt and effective eradication of infection, amelioration of signs and symptoms, and reduction of morbidity and mortality. Key elements include initiation of appropriate anti-infective and supportive care, and prevention of disease through timely introduction of vaccination and chemoprophylaxis. Understanding appropriate selection of anti-infective agents and the issues surrounding their CNS penetration will assist in meeting the goals of treatment.

General Approach to Treatment, Nonpharmacologic and Supportive Therapy

⑤Until a pathogen is identified, prompt empiric antibiotic coverage is needed. Based on the patient's profile (ie, allergies, age, and concurrent medical conditions), extent of antibiotic CNS penetration, spectrum of activity, and local susceptibility patterns, appropriate recommendations should be made. Therapy should last at least 48 to 72 hours or until an infectious process has been ruled out (Tables 128-2 and 128-3).[26,27,36]

TABLE 128-2

Bacterial Meningitis: Most Likely Etiologies and Empiric Therapy by Age Group

Age	Most Likely Organisms	Empirical Therapy[a]
<1 month	*S. agalactiae* Gram-negative enterics[b] *L. monocytogenes*	Ampicillin + cefotaxime *or* ampicillin + aminoglycoside
1-23 months	*S. pneumoniae* *N. meningitidis* *H. influenzae* *S. agalactiae*	Vancomycin[c] + third-generation cephalosporin (cefotaxime *or* ceftriaxone)
2-50 years	*N. meningitidis* *S. pneumoniae*	Vancomycin[c] + third-generation cephalosporin (cefotaxime *or* ceftriaxone)
>50 years	*S. pneumoniae* *N. meningitidis* Gram-negative enterics[b] *L. monocytogenes*	Vancomycin[c] + ampicillin + third-generation cephalosporin (cefotaxime *or* ceftriaxone)

[a] Data from References [26,27].

[b] *E. coli*, *Klebsiella* spp., *Enterobacter* spp. common.

[c] Vancomycin use should be based on local incidence of penicillin-resistant *S. pneumoniae* and until cefotaxime or ceftriaxone minimum inhibitory concentration results are available.

Strength of recommendation: (A) Good evidence to support a recommendation for use; should always be offered. (B) Moderate evidence to support a recommendation for use; should generally be offered.[26]

Quality of evidence: (i) Evidence from one or more properly randomized, controlled trial. (ii) Evidence from one or more well-designed clinical trial, without randomization; from cohort or case-controlled analytic studies (preferably from one or more center) or from multiple time-series. (iii) Evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees.[26]

TABLE 128-3

Penetration of Anti-infective Agents into the CSF[a]

Therapeutic Levels in CSF With or Without Inflammation	
Acyclovir	Levofloxacin
Chloramphenicol	Linezolid
Ciprofloxacin	Metronidazole
Fluconazole	Moxifloxacin

Flucytosine	Pyrazinamide
Foscarnet	Rifampin
Fosfomycin	Sulfonamides
Ganciclovir	Trimethoprim
Isoniazid	Voriconazole
Therapeutic Levels in CSF With Inflammation of Meninges	
Ampicillin ± sulbactam	Imipenem
Aztreonam	Meropenem
Cefepime	Nafcillin
Cefotaxime	Ofloxacin
Ceftazidime	Penicillin G
Ceftriaxone	Piperacillin/tazobactam[b]
Cefuroxime	Pyrimethamine
Colistin	Quinupristin/dalfopristin
Daptomycin	Ticarcillin ± clavulanic acid[b]
Ethambutol	Vancomycin
Nontherapeutic Levels in CSF With or Without Inflammation	
Aminoglycosides	Cephalosporins (second generation)[d]
Amphotericin B	Doxycycline[e]
β-Lactamase inhibitors[c]	Itraconazole[f]
Cephalosporins (first generation)	

[a] Data from Reference [36].

[b] May not achieve therapeutic levels against organisms with higher MIC, as in *P. aeruginosa*. Tazobactam does not penetrate BBB.

[c] Includes clavulanic acid, sulbactam, and tazobactam.

[d] Cefuroxime is an exception.

[e] Documented effectiveness for *B. burgdorferi*.

[f] Achieves therapeutic concentrations for *Cryptococcus neoformans* therapy.

⑥ Acute bacterial meningitis is a neurologic emergency. An empiric antimicrobial therapy should be initiated as soon as possible after a diagnosis is suspected.[26] The first dose of antibiotics should not be withheld, even when lumbar puncture is delayed or neuroimaging is being performed. It is strongly recommended that the time period from suspected diagnosis to initiation of antibiotic treatment should not exceed 1 hour.[27]

Supportive care, particularly early in the course of treatment, is important. Administration of fluids, electrolytes, antipyretics, and analgesics may be indicated for patients presenting with a possible CNS infection. Additionally, venous thromboembolism prophylaxis, antiepileptic therapy, and ICP monitoring may be needed. Patients may require the administration of osmotic diuretics such as mannitol 25% or hypertonic saline to maintain an ICP of less than 15 mm Hg (2 kPa) and a cerebral perfusion pressure of 60 mm Hg (8 kPa) or more. Other supportive care measures may include respiratory and circulatory supports, gastrointestinal (GI) care, and maintaining normal body temperature.

Although supportive treatment may be indicated in certain patients with acute bacterial meningitis, the routine use of adjuvant mannitol, acetaminophen, antiepileptic agents, or hypertonic saline is not recommended according to the European guidelines.[27] Furthermore, therapeutic hypothermia and glycerol are contraindicated because they have been associated with a higher mortality rate.[37,38] However, a Cochrane meta-analysis including 1,272 patients (mostly children under 16 years) demonstrated no effect of glycerol on mortality.[39]

⑦ Several factors influence the transfer of antibiotic from capillary blood into the CNS. Notably, antibiotic penetration is increased through inflamed meninges due to damage to tight junctions between capillary endothelial cells and reduction of the activity of energy-dependent efflux pumps in the choroid plexus responsible for movement of penicillins and, to a lesser extent, fluoroquinolones and aminoglycosides (Table 128-3). Antibiotics having low molecular weights are passed more easily through biologic barriers than compounds of higher molecular weight. Furthermore, only nonionized antibiotics at physiologic or pathologic pH are capable of diffusion. Highly lipid-soluble compounds penetrate more readily than water-soluble compounds. Antibiotics not extensively bound to plasma proteins provide a larger free fraction of drug capable of passing into the CSF. However, passage of large, polar antibiotics into the CSF may be assisted by a carrier transport system. Antibiotic dosages in the treatment of CNS infections must be optimized to ensure adequate penetration to the site of infection.

Challenges of CSF penetration were traditionally overcome by direct instillation of antibiotics intrathecally or intraventricularly. Advantages of direct instillation, however, must be weighed against the risks of invasive CNS procedures and adverse effects. Intraventricular delivery may be necessary in patients who have shunt infections that are difficult to eradicate or who cannot undergo surgical management.[26] Antimicrobial agents often utilized for bacterial meningitis treatment have adequate CSF penetration, which has limited the need for direct CNS instillation for this type of infection. The Infectious Diseases Society of America (IDSA) guidelines for healthcare-associated meningitis and ventriculitis recommend considering the use of intraventricular antibiotics only in patients who fail or respond poorly to systemic treatment.[12]

⑧ Although the length of treatment for acute bacterial meningitis is generally based on the causative organism, there is no universally accepted standard (Table 128-4).[12,26,27] Meningitis caused by *S. pneumoniae* has been treated successfully with 10 to 14 days of antibiotic therapy, while cases caused by *N. meningitidis* or *H. influenzae* usually can be treated with a 7-day course. In contrast, a longer duration (21 days or more) has been recommended for patients with *L. monocytogenes*, gram-negative or pseudomonal meningitis. Nonetheless, antibiotic treatments for bacterial meningitis should be individualized, and some patients may require prolonged courses.

TABLE 128-4

Antimicrobial Agents of First Choice and Alternative Choice in the Treatment of Meningitis Caused by Gram-Positive and Gram-Negative Microorganisms

Organism	Antibiotics of First Choice	Alternative Antibiotics	Recommended Duration of Therapy
Gram-Positive Organisms			

Streptococcus pneumoniae[a]			10-14 days
Penicillin susceptible MIC ≤0.06 mcg/mL (mg/L)	Penicillin G or Ampicillin (A-III)	Cefotaxime (A-III), Ceftriaxone (A-III), Cefepime (B-II), or Meropenem (B-II)	
Penicillin resistant MIC >0.06 mcg/mL (mg/L)	Vancomycin[b,c] + Cefotaxime or Ceftriaxone (A-III)	Moxifloxacin (B-I I)	
Ceftriaxone resistant MIC >0.5 mcg/mL (mg/L)	Vancomycin[b,c] + Cefotaxime or Ceftriaxone (A-III)	Moxifloxacin (B-I I)	
Staphylococcus aureus			14-21 days
Methicillin susceptible	Nafcillin or Oxacillin (A-III)	Vancomycin (A-III) or Meropenem (B-III)	
Methicillin resist ant	Vancomycin[b,c] (A-III)	Trimethoprim-sulfamethoxazole or Linezolid (B-III)	
Group B *Streptococcus*	Penicillin G or Ampicillin (A-III) ± Gentamicin[b,c]	Ceftriaxone or Cefotaxime (B-III)	14-21 days
S. epidermidis	Vancomycin[b,c] (A-III)	Linezolid (B-III)	14-21 days[d]
L. monocytogenes	Penicillin G or Ampicillin ± Gentamicin[b,c,e] (A-III)	Trimethoprim-sulfamethoxazole (A-III), Meropenem (B-III)	≥21 days
Gram-Negative Organisms			
Neisseria meningitis			7-10 days
Penicillin susceptible	Penicillin G or Ampicillin (A-III)	Cefotaxime or Ceftriaxone (A-III)	
Penicillin resistant	Cefotaxime or Ceftriaxone (A-III)	Meropenem or Moxifloxacin (A-I	
Haemophilus influenzae			7-10 days
β-lactamase negative	Ampicillin (A-III)	Cefotaxime (A-III), Ceftriaxone (A-III), Cefepime (A-III) or Moxifloxacin (A-III)	
β-lactamase positive	Cefotaxime or Ceftriaxone (A-I)	Cefepime (A-I) or Moxifloxacin (A-III)	

Enterobacteriaceae[f]	Cefotaxime or Ceftriaxone (A-II)	Cefepime (A-III), Moxifloxacin (A-III), Meropenem (A-III) or Aztreonam (A-III)	21 days
Pseudomonas aeruginosa	Cefepime or Ceftazidime (A-II) ± Tobramycin[b,c] (A-III)	Ciprofloxacin (A-III), Meropenem (A-III), Piperacillin plus Tobramycin[a,b] (A-III), Colistin sulfomethate[g] (B-III), Aztreonam (A-III)	21 days

[a] Data from References [12,26,27].

[b] Direct CNS administration may be considered if failed conventional treatment.

[c] Monitor serum drug levels.

[d] Based on clinical experience; no clear recommendations.

[e] European guidelines recommend adding gentamicin for the first 7 days of treatment.

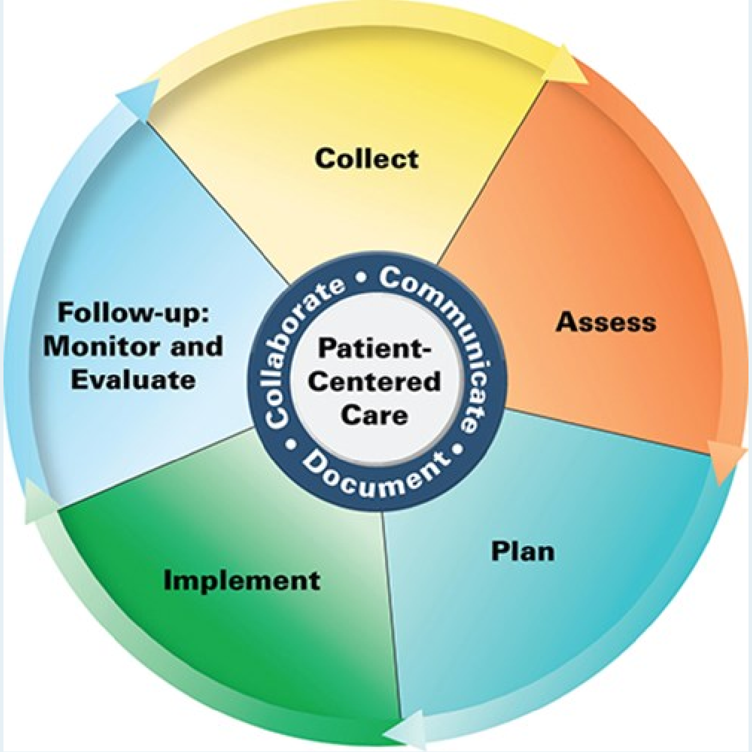
[f] Includes *E. coli* and *Klebsiella* spp.

[g] Should be reserved for multidrug-resistant pseudomonal or Acinetobacter infections for which all other therapeutic options have been exhausted.

See Table 128-2 footnotes for rating scale of evidence.

PATIENT CARE PROCESS

Patient Care Process for CNS Infections



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

The image shows the five fundamental steps included in The Pharmacist's Care Process endorsed by the Joint Commission for Pharmacy Practitioners (2014). The tagline of this process reads collaborate, communicate, and document. The five fundamental steps listed here are collect, assess, plan, implement, and follow-up: monitor and evaluate. All these steps are listed in a circular block diagram.

Collect

- Patient characteristics (eg, age, sex, weight, height, pregnancy/breastfeeding status, allergies)
- Patient medical history (personal and family)
- Social history (eg, alcohol/illicit drug use, recent travel, home residence, exposure to animals) and dietary habits including intake of unpasteurized dairy products
- Current medication use including anti-infective and immunomodulating agents
- Vaccination history (eg, PCV13, PPSV23, Hib, MenACWY, MenB, influenza, COVID-19)
- Objective data
    - Vitals (eg, temperature, blood pressure, pulse, respiratory rate), and laboratories (white blood cell count, lactate, procalcitonin, serum creatinine, blood urea nitrogen)
    - Blood/CSF examination, cultures, gram stain, PCR, 16s rRNA, smear, AFB, serology radiologic imaging (MRI, CT)

Assess

- Presence of risk factors (eg, vaccination history, immunocompromised status, asplenia, recent dental procedure, endocarditis, consumption of unpasteurized dairy products, central venous catheter, CSF shunt)
- Signs and symptoms (eg, temperature >100.4 °F [38 °C], nuchal rigidity, headache, Kernig's and Bruzinski's signs [Figs. 128-4 and 128-5], CSF characteristics [Table 128-1], radiographic evidence, pathogen identification)
- Local susceptibilities of suspected/proven pathogen(s)
- Source control of focal infection (eg, minimally invasive aspiration of brain abscess)
- Barriers for successful completion of therapeutic regimen
- Candidates for chemoprophylaxis

Plan[*]

- Evidence-based empiric drug therapy regimen including anti-infective agent(s) with good CNS penetration (Table 128-3), dose, route, frequency, and duration (see Tables 128-2 and 128-5, the sections "Healthcare-Associated Ventriculitis and Meningitis," "Bacterial Brain Abscess," "Viral Encephalitis," and "CNS Infections in Special Populations").
- Definitive anti-infective therapy if specific pathogen identified (Tables 128-4 and 128-5, sections as above)
- Corticosteroid use when indicated
- Monitoring parameters including efficacy (eg, fever, mental status, meningismus, white blood cell count, radiologic resolution of focal infection, drug monitoring) and safety (eg, renal function, drug-drug interactions); frequency and timing of follow-up
- Patient education (eg, purpose of treatment, invasive procedures, drug-specific information)
- Referrals to other providers when appropriate (eg, infectious diseases, neurologist, interventional radiologist)

Implement[*]

- Provide patient education regarding all elements of treatment plan
- Ensure effective transitions of care
- Schedule follow-up if treatment continues as outpatient (eg, SCr, adherence assessment, radiographic imaging)

Follow-up: Monitor and Evaluate

- Resolution of CNS infection symptoms (eg, fever, nuchal rigidity, headache, altered mental status)
- Presence of adverse effects (eg, acute renal injury, electrolyte abnormalities, QT interval prolongation)
- Patient adherence to treatment plan using multiple sources of information
- Duration of therapy based on evidence-based guidelines, clinical and radiologic progress

[*] *Collaborate with patient, caregivers, and other healthcare professionals.*

TABLE 128-5

Dosing of Anti-infective Agents by Age Group

Agent	Infants and Children	Adults	Monitoring/Comments
Antibacterial			
Ampicillin	75 mg/kg every 6 h	2 g every 4 h	
Aztreonam	40mg/kg every 6-8 h	2 g every 6-8 h	Alternative for severe penicillin allergy
Cefepime	50 mg/kg every 8 h	2 g every 8 h	Consider prolonged infusion
Cefotaxime	75 mg/kg every 6-8 h	2 g every 4-6 h	Preferred in neonates
Ceftazidime	50 mg/kg every 8 h	2 g every 8 h	
Ceftriaxone	100 mg/kg daily	2 g every 12 h	Avoid in neonates
Ciprofloxacin	10 mg/kg every 8 h	400 mg every 8-12 h	Consider higher doses for *P. aeruginosa*
Colistin	5 mg/kg/day (package insert dosing)	5 mg/kg/day (package insert dosing)	Consider intraventricular doses Only for MDR organisms Monitor renal function
Gentamicin	2.5 mg/kg every 8 h	2 mg/kg every 8 h or 5-7 mg/kg daily	TDM is recommended
Levofloxacin	—	750 mg daily	May prolong QTc
Linezolid	10 mg/kg every 8-12 h	600 mg every 12 h	May cause thrombocytopenia and peripheral neuropathy

Meropenem	40 mg/kg every 8 h	2 g every 8 h	Consider prolonged infusion
Moxifloxacin	—	400 mg daily	May prolong QTc
Oxacillin/Nafcillin	50 mg/kg every 6 h	2 g every 4 h	Nafcillin preferred if renal dysfunction
Penicillin G	0.05 million Units/kg every 4 h	4 million Units every 4 h	
Polymyxin B	—	1.25-1.5 mg/kg every 12 h	Only for MDR organisms No data in pediatric patients
Tobramycin	2.5 mg/kg every 8 h	2.5 mg/kg every 8 h or 5-7 mg/k g daily	TDM is recommended Monitor renal function
Trimethoprim-sulfamethoxazole	5 mg/kg every 6-12 h	5 mg/kg every 6-12 h	Dose based on trimethoprim
Vancomycin	15 mg/kg every 6 h	15-20 mg/kg every 8-12 h	TDM is recommended Monitor renal function
Antifungals			
Conventional Amphotericin B	1 mg/kg daily	0.7-1 mg/kg daily	Monitor renal function Maintain adequate hydration
Lipid amphotericin B	3-5 mg/kg once daily	3-5 mg/kg daily	Monitor renal function Maintain adequate hydration
Flucytosine	25 mg/kg every 6 h	25 mg/kg every 6 h	Consider TDM to avoid bone marrow suppression
Fluconazole	6-12 mg/kg daily	400-800 mg daily	Monitor liver function
Voriconazole	9mg/kg every 12 h × 2 doses then 8 mg/kg every 12 h	6 mg/kg every 12 h × 2 doses then 4 mg/kg every 12 h	Consider TDM Many drug-drug interactions Monitor liver function
Antivirals			
Acyclovir	10-20 mg/kg every 8 h	10-20 mg/kg every 8 h	Monitor renal function Maintain adequate hydration
Ganciclovir	—	5 mg/kg every 12 h	Monitor renal function
Foscarnet	—	60 mg/kg every 8 h or 90 mg/kgevery 12 h	Monitor renal function Maintain adequate hydration

TDM, therapeutic drug monitoring. Data from References [12,14,26,27].

ACUTE BACTERIAL MENINGITIS

Causative Organisms

Streptococcus pneumoniae (Pneumococcus or Diplococcus)

9 *S. pneumoniae* continues to be the leading cause of community-acquired bacterial meningitis in patients 2 months of age or older. It accounts for approximately 40% to 50% of bacterial meningitis cases in the United States, with an overall case fatality rate of ~8% to 22%.[2,9,40] Despite declining rates of pneumococcal meningitis since the introduction of PCV7 and PCV13 vaccinations in 2000 and 2010, respectively, case fatality rate has not significantly changed from the pre-PCV7 era.[2,41] Pneumonia, bloodstream infection, endocarditis, CSF leak secondary to head trauma, splenectomy, alcoholism, sickle cell disease, and bone marrow transplantation may predispose the patient to the development of pneumococcal meningitis. Coma, hearing impairment, and seizures are common neurologic complications due to *S. pneumoniae* meningitis.

5 Based on resistance patterns, penicillin should not be used as empiric therapy if *S. pneumoniae* is suspected. Furthermore, appropriate Clinical Laboratory Standards Institute (CLSI)-approved testing of all CSF isolates for penicillin resistance is recommended. Ceftriaxone and cefotaxime have served as alternatives to penicillin in the treatment of penicillin-nonsusceptible pneumococci. Of note, higher minimum inhibitory concentration (MIC) with cephalosporins and higher cephalosporin resistance rates were noted in penicillin-resistant isolates, with the exception of ceftaroline.[42] Therapeutic approaches to cephalosporin-resistant pneumococci include the addition of vancomycin or, to a lesser extent, rifampin. The combination of vancomycin and ceftriaxone can be used as empirical treatment until antimicrobial susceptibility data are available.[25-27]

Given the limited therapeutic options for penicillin- and cephalosporin-resistant pneumococcal meningitis, newer agents have been evaluated. Meropenem is approved for the treatment of bacterial meningitis in children aged 3 months and older and has shown similar clinical and microbiologic efficacies to cefotaxime or ceftriaxone. Meropenem is recommended as an alternative to a third-generation cephalosporin in penicillin-nonsusceptible isolates. Some caution is warranted with the use of imipenem for CNS infections, given the risk of drug-induced seizures, especially when doses are not properly adjusted for declining renal function. Of note, seizures may be caused by meningitis itself or imipenem, and the cause is often difficult to differentiate. Levofloxacin and moxifloxacin represent additional therapeutic options with favorable activity against multidrug-resistant pneumococci and good penetration into the CSF.[12,43]

Intravenous linezolid, daptomycin, and ceftaroline have also emerged as viable therapeutic options for treating multidrug-resistant gram-positive infections. Linezolid in combination with ceftriaxone has been used to treat a limited cases of pneumococcal meningitis with outcomes similar to standard treatment.[44] Further research is required to delineate the clinical utility of therapeutic options such as daptomycin and ceftaroline and determine their place in therapy.[45,46]

Pneumococcal vaccines help reduce the risk of invasive pneumococcal disease (IPD). Virtually all serotypes of *S. pneumoniae* exhibiting intermediate or complete resistance to penicillin are included in the 23-serotype pneumococcal polysaccharide vaccine (PPSV23). Use of the heptavalent pneumococcal conjugate vaccine (PCV7), introduced in 2000, significantly reduced the incidence of invasive pneumococcal infections, including sepsis and meningitis. However, in the decade following its introduction, rate of invasive disease caused by non-PCV7 strains increased considerably, especially serotype 19A, leading to the development of a newer vaccine with expanded coverage. In 2010, the FDA approved PCV13 to replace PCV7. In the first 3 years after the introduction of PCV13 in the United States, investigators estimated over 30,000 cases of IPD and 3,000 deaths were potentially averted.[47] Between 1998 and 2018, rates of IPD in the United States among children and adults have steadily decreased since PCV7 and PCV13 introductions.[48]

For current recommendations on vaccinations against pneumococcal disease and high-risk groups, refer to Chapter 147, “Vaccines, Toxoids, and Other Immunobiologics” in this book and the current guidelines by the Advisory Committee on Immunization Practices (ACIP).

Neisseria meningitidis (Meningococcus)

1 *N. meningitidis* is a leading cause of bacterial meningitis among children and young adults in the United States and around the world.[2,49] Incidence of meningococcal disease in the United States has been declining from 1.2 cases per 100,000 population in the 1990s to 0.1 cases per 100,000 population in 2018. Incidence peaks in infants <1-year-old (0.93 cases per 100,000 population) with a second peak in adolescents and young adults 16

to 23 years of age (0.23 cases per 100,000 population).[50] Five of the thirteen serogroups of *N. meningitidis* (A, B, C, Y, and W) are primarily responsible for invasive meningococcal disease. The proportion of cases caused by each serogroup varies by age group. Serogroup B causes ~65% of meningococcal disease among children <5 years old.[49]

N. meningitidis is spread by direct person-to-person close contact, including respiratory droplets and pharyngeal secretions. Close contacts of patients contracting meningococcal meningitis are at an increased risk of developing meningitis. Secondary cases of meningitis usually develop within the first week following exposure but may take up to 60 days after contact with the index case.[11] Clusters of disease are associated with crowding as in schools, dormitories, and military barracks. Other significant risk factors for meningococcal disease include complement deficiency, anatomic or functional asplenia, HIV infection, and passive or active smoking.[11]

The presence of petechiae may be the primary clue that the underlying pathogen is *N. meningitidis*.[25] Patients may also have an obvious or subclinical picture of disseminated intravascular coagulation (DIC). Deafness unilaterally or bilaterally may develop early or late in the disease course.

5 Third-generation cephalosporins (ie, cefotaxime and ceftriaxone) are the recommended empiric treatment for meningococcal meningitis (Table 128-4).[26,27] When final culture results are available, penicillin G or ampicillin is recommended for penicillin-susceptible isolates. Meropenem and fluoroquinolones are also suitable alternatives for the treatment of penicillin nonsusceptible meningococci. The recommended duration of therapy is typically 7 days if there is good clinical response.[26] Antimicrobial chemoprophylaxis of close contacts should be started as soon as possible (ideally <24 hours after identification of the index patient). There was an 84% reduction in the risk of invasive meningeal disease for 30 days after the index case when household contacts were given chemoprophylaxis. Ciprofloxacin and rifampin are the two most used chemoprophylactic agents, although antibiotic resistance can develop when meningococcal isolates are exposed to rifampin.[51] For further discussion on who should receive prophylaxis, interested readers can refer to current recommendations by the Centers for Disease Control and Prevention (CDC).[11]

Two types of meningococcal vaccines are available in the United States: two quadrivalent polysaccharide protein conjugate vaccine directed against serogroups A, C, W, and Y and two MenB vaccines directed against serogroup B meningococcal vaccine. The quadrivalent meningococcal conjugate vaccine is recommended for all people 11 to 12 years old with a booster dose at 16 years of age. Among adolescents ages 13 to 17 years old in the United States, 88.9% received ≥1 dose of the MenACWY vaccine in 2019.[52] Additionally, the outer membrane vesicle meningococcal B vaccine (MeNZB) is being assessed for vaccine effectiveness against gonorrhea in young adults, due to the 80% to 90% genetic homology in primary sequences between *N. gonorrhoeae* and *N. meningitidis*.[53] For full details on vaccine availability and vaccination recommendations in various age groups and for those with significant risk factors, refer to Chapter 147, "Vaccines, Toxoids, and Other Immunobiologics" in this book and the current recommendations from the ACIP.

Haemophilus influenzae Type b

1 Widespread vaccination of infants and children has resulted in a dramatic decline in the global incidence of Hib meningitis from 31 to 5 per 100,000 children aged < 5 years in 2000 and 2015, respectively.[54] Similarly, the global Hib meningitis case fatality ratio fell from 44% in 2000 to 23% in 2015. Interested readers can refer to Chapter 147, "Vaccines, Toxoids, and Other Immunobiologics" in this book for information on recommended Hib vaccine dosing and administration schedules. In neonates, infection is acquired intrapartum by aspiration of amniotic fluid or by contact with genital tract secretions containing the organism. In older children and adults, Hib meningitis should suggest the presence of other underlying conditions, including otitis media, epiglottitis, sinusitis, pneumonia, diabetes mellitus, sickle cell, asplenia, alcoholism, and immunodeficiency.

5 Third-generation cephalosporins (cefotaxime and ceftriaxone) are the drugs of choice for empiric therapy for Hib meningitis as they are active against β-lactamase–producing and non-β-lactamase–producing strains. Cefepime and fluoroquinolones are suitable alternatives regardless of β-lactamase activity. Ampicillin can be used if the isolate is susceptible. Beta-lactamase-negative, ampicillin-resistant strains of *H. influenzae* have been described and some experts recommend caution in using ampicillin when the penicillin minimum inhibitory concentration is 1 to 2 mcg/mL.[55] Recommended duration of treatment is 7 days (adults) or 7 to 10 days (children).[26,27]

Dexamethasone is beneficial for treatment of infants and children with Hib meningitis to diminish the risk of hearing loss, if given before or concurrently with the first dose of antimicrobial agent(s).[26,27,56] All invasive (including meningitis) cases should be reported to the local public health department.

⑨ Chemoprophylaxis is indicated to reduce the risk of secondary invasive Hib disease in close contacts by eliminating nasopharyngeal and oropharyngeal carriages of *H. influenzae*. For prophylaxis, rifampin should be administered orally (once a day for 4 days; 20 mg/kg/dose; maximum, 600 mg). The dose for infants younger than 1 month is not established; some experts recommend lowering the dose to 10 mg/kg.[56,57]

Streptococcus agalactiae (Streptococcus Group B)

Streptococcus group B (GBS) is a leading cause of meningitis in neonates and young infants, with a case fatality rate of 7.3% in pediatric patients and 20.8% in adult patients.[2] Neurologic sequelae include sight or hearing loss and cerebral palsy. Neonates acquire this infection through vertical transmission while passing through the vaginal canal during birth. GBS is an inhabitant of the human GI and genitourinary tracts. Maternal GBS colonization worldwide was shown to be 18% with regional variation from 11% to 35%.[58]

Early onset GBS infection occurs within the first 24 hours of life (range 0-6 days), whereas late-onset disease typically occurs from 7 to 89 days of age).[59] Universal prenatal screening and intrapartum antimicrobial prophylaxis of GBS-colonized pregnant women have significantly decreased the rate of early onset invasive disease.[60] However, late-onset disease cannot not be prevented by intrapartum antimicrobial prophylaxis. Recommended agents for intrapartum prophylaxis are penicillin G or ampicillin, cefazolin (if penicillin allergy with low risk of anaphylaxis), clindamycin (if penicillin allergy with high risk of anaphylaxis and GBS isolate is known to be susceptible to clindamycin), or vancomycin (if penicillin allergy with high risk of anaphylaxis and GBS isolate not susceptible, or unknown susceptibility, to clindamycin). Intrapartum antibiotic prophylaxis should be started promptly to achieve the optimal antibiotic treatment window of at least 4 hours before birth.[61]

Maternal immunization represents a nonantibiotic strategy to prevent both early and late-onset GBS infection and has been a focus of the WHO.[62] There are currently no licensed GBS vaccines, although some promising conjugate vaccine candidates have been tested for safety and immunogenicity in phase I and II trials.

⑤ Ampicillin plus an aminoglycoside is the treatment of choice for a newborn infant with presumptive early onset GBS meningitis. Empiric treatment for late-onset meningitis differs by postnatal age at the time of evaluation. When group B streptococci are identified in culture, penicillin G is the drug of choice, with ampicillin as an acceptable alternative therapy.[59] For infants with uncomplicated meningitis, 14 days of treatment is satisfactory, but longer periods of treatment may be necessary for patients with prolonged or complicated courses; ventriculitis should be treated for at least 4 weeks. Ampicillin or penicillin G is the recommended agent for confirmed GBS meningitis in adults. Addition of an aminoglycoside could also be considered.[26] Alternative agents are third-generation cephalosporins and vancomycin. For adults with meningitis, the recommended duration of antibiotics is 14 to 21 days.

Listeria monocytogenes

L. monocytogenes is a facultative anaerobic, gram-positive, diphtheroid-like organism that multiplies intracellularly. Meningitis due to *L. monocytogenes* primarily affects neonates, alcoholic or immunocompromised individuals (including pregnant women), and the elderly. Invasive infections in healthy young individuals remain rare. *L. monocytogenes* is implicated in approximately 10% of meningitis cases in patients older than 65 years of age and carries a case fatality rate of approximately 18% in the United States.[2]

Transmission usually involves colonization of the patient's gastrointestinal tract with the organism, which then penetrates the gut lumen to seed the bloodstream. Soft cheeses and raw produce are common causes of listeriosis outbreaks. Coleslaw, unpasteurized milk, ready-to-eat foods, and raw beef and poultry have also been identified as sources of this foodborne pathogen. Invasive disease includes bacteremia, meningitis, meningoencephalitis, or cerebritis. Infection of the CNS may be diffuse or localized.

⑤ ⑧ Treatment of *L. monocytogenes* meningitis should consist of penicillin G or ampicillin. The addition of aminoglycoside is also recommended in proven infection for both children and adults. Trimethoprim-sulfamethoxazole and meropenem are recommended alternative agents, whereas there is less clinical experience with linezolid and fluoroquinolones. Despite *in vitro* activity against *L. monocytogenes*, intravenous vancomycin has been associated with high failure rates in patients with *L. monocytogenes* meningitis. Also, third-generation cephalosporins lack *in vitro* activity against *L. monocytogenes*. Patients should be treated for a minimum of 21 days.[26,27]

A national prospective study from France of 252 cases of neurolisteriosis showed significantly greater mortality in patients who received adjunctive dexamethasone within the first 24 hours.[63] This deleterious effect suggests that adjunctive dexamethasone should be avoided in the treatment of neurolisteriosis.

Dexamethasone as an Adjunctive Treatment for Acute Bacterial Meningitis

In addition to antibiotics, dexamethasone is a commonly used adjunctive therapy in the treatment of acute bacterial meningitis to immunomodulate the inflammatory response. Corticosteroids inhibit the production of TNF and IL-1, both potent proinflammatory cytokines.

A systematic review of 25 randomized controlled trials involving 4,121 participants showed that corticosteroid use in bacterial meningitis was associated with lower rates of hearing loss and short-term neurological sequelae in adults and children, but there was no mortality benefit in high-income countries. No beneficial effects were observed in low-income countries. Additionally, subgroup analyses demonstrated a 16% reduction in overall mortality in pneumococcal meningitis and a 66% reduction in severe hearing loss in children with *H. influenzae* meningitis.[64]

① Routine use of dexamethasone in meningitis is not without controversy. A potential concern is that adjunctive dexamethasone therapy may reduce the penetration of antibiotics into the CSF by inhibiting or reducing meningeal inflammation. Appropriate concentrations of vancomycin in CSF may be obtained even when adjunctive dexamethasone is used, but the small number of subjects studied limits the generalization of these findings.[65] Recommendations by practice guidelines call for the use of adjunctive dexamethasone in infants and children (6 weeks of age and older) with *H. influenzae* meningitis.[26] The recommended intravenous dose is 0.15 mg/kg every 6 hours for 2 to 4 days, initiated 10 to 20 minutes prior to or concomitant with the first dose of antibiotics. In infants and children with pneumococcal meningitis, adjunctive dexamethasone may be considered after weighing the potential benefits and possible risks.[26,56] If pneumococcal meningitis is suspected or proven, adults should receive dexamethasone 0.15 mg/kg (up to 10 mg) every 6 hours for 2 to 4 days with the first dose administered 10 to 20 minutes prior to first dose of antibiotics. It is often difficult to ascertain the responsible pathogen on presentation. Therefore, some clinicians and the European guidelines recommend initiating dexamethasone in all patients (adults and children) presenting with suspected or proven community-acquired bacterial meningitis and consider discontinuation only if pathogens other than *H. influenzae* or *S. pneumoniae* are identified. Another difference between the U.S. and European guidelines is that according to the European guidelines, dexamethasone can still be administered up to 4 hours after initiation of antibiotics.[27] Adjunctive dexamethasone in neurolisteriosis has been associated with reduced survival. Therefore, adjunctive dexamethasone should be discontinued if the meningitis is found to be caused by *L. monocytogenes*.[63]

HEALTHCARE-ASSOCIATED VENTRICULITIS AND MENINGITIS

Healthcare-associated meningitis and ventriculitis, formerly referred to as nosocomial meningitis, is a subclass of bacterial meningitis that largely occurs in neurosurgical patients.[12] The disease process in these patients can be more indolent compared to those with community-acquired bacterial meningitis. The most likely pathogens associated with CSF shunt and drain infections are coagulase-negative staphylococci (especially *Staphylococcus epidermidis*), *S. aureus, Propionibacterium* (now *Cutibacterium*) *acnes*, and gram-negative bacilli; including *E. coli*, Enterobacter species, Citrobacter species, Serratia species, and *Pseudomonas aeruginosa*. In the presence of prosthetic devices, some of the microorganisms form biofilms which compromise antibiotic penetration.

Diagnosis of healthcare-associated meningitis and ventriculitis can be challenging and should focus on CSF fluid analysis and culture. However, patients may have only modest abnormalities in CSF cell counts. Additionally, CSF Gram-stain may be unreliable—particularly in the setting of systemic antibiotic exposure. If possible, antibiotic therapy should be delayed until CSF can be recovered for culture. A negative CSF culture following antimicrobial therapy is not sufficient to exclude healthcare-associated meningitis or ventriculitis.[66] Use of extended hold cultures is encouraged to increase recovery of slow-growing pathogens such as *C. acnes*. If a CSF drain or shunt is removed due to possible infection, then these components should be cultured as well. Blood cultures may be considered in those with ventriculopleural or ventriculoperitoneal shunts but are recommended in those with ventriculoatrial shunts.[12] 1-3-β-D-glucan may be useful in diagnosing fungal meningitis and ventriculitis because of the low sensitivity of CSF culture for fungal pathogens.[67]

Empiric use of broad-spectrum antibiotic therapy is critical for the treatment of healthcare-associated meningitis and ventriculitis because of the variety of organisms implicated in these cases. Empiric treatment should include intravenous vancomycin coupled with an anti-pseudomonal β-lactam such as meropenem, cefepime, or ceftazidime. All agents should be dosed to maximize CNS penetration.[12] Piperacillin-tazobactam is not recommended given the suboptimal CNS penetration of tazobactam. Continuous infusion vancomycin may optimize vancomycin exposure in the CSF but clinical data remain scant.[68]

Once culture results are available, antibiotic therapy can be tailored. Staphylococcus spp. are important causative pathogens in healthcare-associated meningitis and ventriculitis, particularly among patients with intracranial or spinal hardware. For methicillin-susceptible *S. aureus* (MSSA), the treatment of choice is nafcillin or oxacillin. For methicillin-resistant *S. aureus* (MRSA), vancomycin is preferred. Rifampin may be considered for staphylococcal infections if the isolate is susceptible. Rifampin is indicated when there is hardware present for optimal biofilm penetration. If β-lactam or vancomycin therapy is not possible then clinicians may consider linezolid or trimethoprim-sulfamethoxazole. Daptomycin may also be considered although given its limited CNS penetration aggressive dosing is probably necessary (eg, 10-12 mg/kg/day).[12,69]

⑤The treatment of meningitis due to *P. aeruginosa* remains a challenge because antibiotics showing good antibacterial activity, such as antipseudomonal penicillins and aminoglycosides, penetrate the CSF moderately or poorly (Table 128-3). Initially, cases of *P. aeruginosa* meningitis should be treated with an extended-spectrum β-lactam such as ceftazidime or cefepime, or alternatively aztreonam, ciprofloxacin, or meropenem depending on local susceptibility patterns. The addition of an aminoglycoside, usually tobramycin, to one of the aforementioned agents can also be considered. Since aminoglycosides penetrate the CSF poorly, their inclusion is to predominantly aid in the treatment of extracerebral infections.

Multidrug-resistant *P. aeruginosa*, Acinetobacter, and carbapenem-resistant Enterobacterales infections are of concern to clinicians because of the limited therapeutic options available. This concern has led to the reemergence of the use of older antibiotics, such as colistin and polymyxin B. Colistin can be used, both intravenously and intrathecally, in the treatment of multidrug-resistant *P. aeruginosa* or Acinetobacter CNS infections. The use of colistin should be reserved for only the most severe cases.

New cephalosporin-β-lactamase inhibitor combination agents (ceftolozane-tazobactam and ceftazidime-avibactam) have yet to be formally studied in patients with CNS infections, but may represent alternative therapies for multidrug resistant gram-negative organisms. For instance, ceftazidime/avibactam resulted in several successful treatments of meningitis caused by a KPC-producing *Klebsiella pneumoniae*.[70,71] Ceftaroline, a novel cephalosporin with affinity for PBP2a has shown promise in a case series of *S. pneumoniae* and *S. aureus* meningitis as well as three other case reports of MRSA meningitis/ventriculopleural shunt infections.[45,72-74] The pharmacokinetic properties of ceftaroline suggest it is probably reliable for CNS infections, particularly if using every 8-hour dosing.

Other gram-negative organisms causing meningitis, excluding *P. aeruginosa* and Acinetobacter spp., most likely can be treated with a third- or fourth-generation cephalosporin, such as cefotaxime, ceftriaxone, ceftazidime, or cefepime. Ceftazidime, however, may not be the best choice of empiric monotherapy for situations where the offending organism is unknown initially due to lack of reliable gram-positive activity. Cefotaxime should be used in place of ceftriaxone in the neonatal period because of the potential of ceftriaxone to displace bilirubin from its albumin-binding sites. Trimethoprim-sulfamethoxazole may offer utility for ventriculitis and meningitis caused by Enterobacterales, given that its penetration into the CSF does not depend on meningeal inflammation. Fluoroquinolones, such as ciprofloxacin, exhibit good penetration into the CSF and are recommended as alternative agents for the treatment of susceptible gram-negative bacilli, including *P. aeruginosa*.

For patients with documented or suspected fungal meningitis or ventriculitis, empiric lipid formulation of liposomal amphotericin B in combination with flucytosine is recommended.[12,75] Once susceptibility is confirmed, fluconazole may be used for Candida spp. recovered from CSF. Echinocandins are large molecules that penetrate into the CNS poorly and are not recommended for fungal meningitis or ventriculitis. For suspected or confirmed Aspergillus spp., the treatment of choice is voriconazole targeting a serum trough level of 2 to 5 mg/L (6 to 14 μmol/L).[12,76]

⑧Some patients with meningitis or ventriculitis respond poorly to systemic antibiotic therapy. For these patients intraventricular therapy should be considered. Numerous antimicrobials can be given intraventricularly, including amikacin, amphotericin B deoxycholate, colistimethate sodium, daptomycin, gentamicin, polymyxin B, quinupristin/dalfopristin, tobramycin, and vancomycin. There is no consensus on the dose of intraventricular antimicrobial that should be used; however, some general recommendations are available.[12] If used, intraventricular antibiotic therapy requires vigilance in preparation and administration. Preservative-free product and diluents should be used unless no preservative-free products exist. For patients receiving antimicrobial therapy through a ventricular drain, the drain should be clamped for 15 to 60 minutes to allow antimicrobial equilibration throughout the CSF.

CSF cultures may remain positive for several days or more with a regimen that eventually will be curative. Therapeutic efficacy can be monitored through bacterial colony counts every 2 or 3 days, which should decrease progressively over the period of therapy. Duration of therapy for healthcare-associated meningitis and ventriculitis is based on clinical response and the offending pathogen. For instance, for *P. acnes* and coagulase-negative Staphylococcal spp., IDSA guidelines recommend 10 to 14 days. For *S. aureus* and gram-negative pathogens 14 days or longer is recommended. For those with persistently positive CSF cultures therapy should continue for 10 to 14 days following the last positive culture.[12]

Finally, another important opportunity for antibiotic optimization exists for patients with external ventricular drains (EVDs). Patients with EVD are often given systemic antibiotic therapy (eg, cefazolin) for infection prophylaxis for the duration of EVD placement to prevent ventriculostomy-related infections. However, the Neurocritical Care Society recommended against this practice citing the potential for harm (eg, *Clostridioides difficile* and antimicrobial-resistant pathogens) from the lack of efficacy attributable to antibiotic prophylaxis.[77] Instead the authors recommend administering one dose of antimicrobials prior to EVD insertion, avoiding routine CSF sampling, and using antibiotic-impregnated EVD catheters. Current guidelines also recommend against extended antibiotic prophylaxis following EVD insertion.[12]

BACTERIAL BRAIN ABSCESS

Brain abscess is a life-threatening focal infection of the brain that begins as a localized area of cerebritis and develops into a collection of pus surrounded by a well-vascularized capsule.[78] In immunocompetent patients, bacteria account for >95% of brain abscesses. Bacteria enter the brain either through contiguous spread (eg, following infection in the oropharynx, middle ear, paranasal sinuses, or neurosurgical procedures and cranial trauma), or hematogenous spread due to distant infections (eg, infective endocarditis, congenital heart disease, dental infection, or pulmonary abscess). Abscess occurs most commonly in the frontal lobe, but can occur in any location.[79] Mortality rates have declined significantly in the past 50 years, with 70% of survivors expected to have no to minimal neurologic sequelae, although data on long-term functional and neuropsychological evaluation are lacking.[80]

②The clinical presentation varies depending on the number, size, and location of the abscess, and diagnosis can be challenging due to this variable presentation. Headache, mental status changes, focal neurologic deficits, and fever are the most common symptoms of brain abscess. Brain imaging is the cornerstone for the diagnosis of brain abscess, with MRI being the preferred modality over contrast-enhanced CT due to better resolution and differentiation of abscesses from tumors. Blood samples should be collected prior to initiation of antibacterial treatment for anaerobic and aerobic cultures, molecular biology, serology, and other diagnostic tests.

The etiology of brain abscess depends on the initial site of infection and the immune state of the host. Abscesses arising from spread of infection from oropharynx, middle ear, and paranasal sinuses are commonly caused by *S. aureus*, streptococci, and oral anaerobes (eg, Actinomyces spp., Bacteroides spp., Fusobacterium spp., or Peptostreptococcus spp.). Dental infections are associated with abscesses caused by Streptococcus spp. and *Bacteroides fragilis*. Staphylococci and Enterobacterales are commonly involved in postoperative abscesses or those following head trauma. *Toxoplasma gondii, Mycobacterium tuberculosis*, Listeria spp., and Nocardia spp. can also cause brain abscesses and are more commonly seen in immunocompromised patients.[79]

⑤All lesions equal or greater than 2.5 cm in diameter should be stereotactically aspirated or surgically excised and specimens should be sent to the microbiology and pathology laboratory.[78,80] Because brain abscesses are commonly polymicrobial, empiric antimicrobial therapy should include antibiotics with activity against gram-positive, gram-negative, and anaerobic organisms. The antimicrobial agents should penetrate into the abscess cavity and remain active in acidic environments. Most commonly the regimen includes a third- or fourth-generation cephalosporin plus metronidazole. Vancomycin should be added when infection caused by MRSA is suspected. Ceftazidime or cefepime can be used if *P. aeruginosa* is suspected. A carbapenem (such as meropenem) could replace the cephalosporin and metronidazole. In immunocompromised patients, the empiric regimen may be supplemented with voriconazole, and trimethoprim-sulfamethoxazole or sulfadiazine to cover fungi and Nocardia while awaiting definitive results. De-escalation of therapy should occur once a causative organism is identified. Repeated neuroimaging should be performed to monitor for abscess resolution or progression.

Prophylactic anticonvulsant therapy and corticosteroids are not routinely recommended.[80] Corticosteroids are not routinely used in brain abscess, and are typically reserved for use in patients with edema causing increased intracranial pressure, brain shift, or increased risk of cerebral herniation. Intravenous antibiotics have traditionally been administered for 6 to 8 weeks, although shorter or longer durations may be used depending on the clinical and radiologic progress. Given the risk of neurotoxicity with prolonged courses of metronidazole, it may be discontinued once anaerobic pathogens have been ruled out. Oral options can consist of ciprofloxacin, metronidazole, trimethoprim-sulfamethoxazole, and amoxicillin but there is no consensus when transition to oral agents can be safely done.

VIRAL ENCEPHALITIS

Encephalitis refers to inflammation of the brain parenchyma in association with clinical evidence of neurologic dysfunction. “Meningoencephalitis” is a term commonly used to describe meningeal inflammation along with encephalitis. Infectious encephalitis should be distinguished from those patients with encephalopathy (eg, due to metabolic disturbances, intoxications, hypoxia, or systemic infections) or noninfectious encephalitis (eg, postimmunization encephalitis or encephalomyelitis), as they have similar clinical presentations.[14] While a confirmed or probable pathogen is identified in less than 50% of cases, viral etiologies are the most commonly diagnosed.[7,15] Collectively, about 20,000 encephalitis-associated hospitalizations are expected per year in the United States, with a case fatality rate of more than 5%. Of those 20,000 hospitalizations, approximately 20% are due to viral pathogens.

The epidemiology of viral encephalitis in the United States has changed dramatically since the mid-1960s due to the introduction of large-scale polio, rubella, varicella-zoster virus, and mumps immunization programs. The most common causes of viral encephalitis/meningoencephalitis in the United States is enteroviruses, followed by herpes viruses and arboviruses.[7,15,16]

Less common causes include adenoviruses, influenza, rotavirus, corona virus, cytomegalovirus (CMV), varicella-zoster virus, Epstein-Barr virus, West Nile Virus (WNV), and lymphocytic choriomeningitis. In recent years, Powassan, Chikungunya, and Zika viruses have emerged as increasing causes of encephalitis in North America. These arboviruses are transmitted via ticks (Powassan) or mosquitoes (Chikungunya and Zika) and have a diverse spectrum of disease. Of these, Powassan virus has seen the largest increase in incidence; prior to 1999 there was an average of 0.7 cases per year in the United States and Canada. In 2003, the CDC included Powassan virus as a reportable disease, resulting in 181 cases reported between 2010 and 2019, with 43 cases reported in 2019 alone.[81]

Zika virus sparked global attention in 2016 after the first cases of brain developmental disorders in newborns were linked to Zika virus infection of their mothers during pregnancy. Epidemiologic and experimental studies have now provided strong support for causality between Zika virus infection during pregnancy and congenital structural abnormalities of the brain.[82] Since 2019 there have been no confirmed reports of Zika disease transmitted by mosquitoes in the United States.[83] Several vaccine candidates for the prevention of Zika disease are in development, although none are approved for use at this time.

Viral encephalitis is acquired primarily by hematogenous spread or, alternatively, by neuronal spread of the causative pathogen. After entry into the host, viral replication occurs, resulting in dissemination through the reticuloendothelial system or vasculature. Infection of the capillary endothelial cells and choroid plexus may provide a conduit for CNS infections. Viruses such as polio, HSV, and Varicella-zoster virus may also gain access to the CNS by axonal retrograde transmission from peripheral nerve endings. Once a virus gains access to the CNS, the course of infection depends on the virulence of the particular virus and the host immune response. Subsequent neuronal injury is caused by direct cell damage due to viral replication, but inflammatory and immune-mediated responses also contribute to neurological damage.

② In contrast with purulent meningitis, host response to viral encephalitis is mediated primarily through cytotoxic T-lymphocytes. Increases in concentrations of IL-1, IL-6, and interferon (INF) α-, β and γ may occur. The clinical syndrome associated with viral encephalitis generally is independent of viral etiology and may vary depending on the patient’s age. Common signs in adults include headache, mild fever, nuchal rigidity, malaise, drowsiness, nausea, vomiting, and photophobia. Only fever and irritability may be evident in the infant, and acute bacterial meningitis must be ruled out as a cause of fever when no other localized findings are observed in a child. Duration of symptoms generally is 1 to 2 weeks, and specific manifestations outside the meninges can also occur depending on the viral etiology.

Laboratory examination of the CSF usually reveals a pleocytosis with 100 to 1,000 WBC/mm^3 (0.1 × 10^9 - 1 × 10^9/L), which are primarily lymphocytic. However, 20% to 75% of patients with viral encephalitis may have a predominance of polymorphonuclear cells on initial examination of the CSF. On repeat lumbar puncture, 90% of patients presenting initially with a predominance of neutrophils experience a shift to a predominance of mononuclear cells. Other laboratory findings include normal to mildly elevated protein concentrations and normal or mildly reduced glucose concentrations (see Table 128-1).

③As mentioned earlier, pathogens responsible for viral encephalitis are often unidentified. When clinical signs warrant pathogen identification, appropriate laboratory diagnostic techniques, including PCR and serologic testing, should be undertaken. Molecular methods are preferred to conventional laboratory tests, such as viral cultures and brain biopsy, in the diagnosis of viral encephalitis owing to improved sensitivity and specificity, higher yield, and rapid results.[14,84]

Supportive and symptomatic treatments, including seizure control, hemodynamic management, venous thromboembolism prevention, ICP management, and secondary bacterial infection prevention, are of great importance in patients with viral encephalitis due to limited treatment options. Corticosteroid therapy is generally not recommended in most viral encephalitis cases; however, treatment should be considered for patients with cerebral edema and increased ICP.[14]

Although there are numerous pathogenic causes of viral encephalitis, much of the clinical presentation, diagnosis, and treatment are similar. The most commonly isolated viral etiologies are described here. HSV type 1 (HSV1) and type 2 (HSV2) are considered the most common treatable causes of viral encephalitis. Between 2011 and 2014, HSV encephalitis accounted for 8.3% of viral encephalitis-associated hospitalizations.[7,16] HSV1 is associated with encephalitis in adults, whereas HSV2 is associated predominantly with encephalitis in newborns. Sexually active adults may acquire HSV meningitis during or after an attack of genital or rectal HSV, whereas neonates acquire the virus during passage through the vaginal canal of mothers with active HSV infection. HSV PCR on CSF specimens should be performed for all patients with presumed encephalitis. Repeat testing should be considered for patients with an initial negative test after 3 to 7 days.[14] Establishing the correct diagnosis early is paramount due to mortality rates approaching 70% without treatment and, unlike other viral etiologies, effective therapy is available. As a result, empiric therapy of suspected HSV encephalitis is recommended, while results are pending. Delaying antiviral therapy has been consistently associated with increased mortality. Additionally, a clinical decision to treat may need to be made regardless of test results.

Acyclovir is the drug of choice for HSV encephalitis. In adults with normal renal function, acyclovir is usually administered as 10 mg/kg intravenously every 8 hours for 2 to 3 weeks.[14,84] Higher doses of acyclovir (up to 20 mg/kg intravenously every 8 hours) have been used in neonates and are associated with lower mortality rates.[85] HSV resistance to acyclovir has been reported with increasing incidence, particularly in immunocompromised patients with prior or chronic exposures to acyclovir, ranging from 3.5% to 10%.[86] The alternative treatment for acyclovir-resistant HSV is foscarnet. The dose for patients with normal renal function is 40 to 60 mg/kg every 8 to 12 hours for 3 weeks, with the higher dose typically reserved for HIV-infected individuals.[14,84] Ensuring adequate hydration is imperative to decrease risk of acyclovir- and foscarnet-induced nephrotoxicity. In addition, patients receiving foscarnet should be monitored for seizures related to alterations in plasma electrolyte levels. Adult patients who completed standard initial HSV encephalitis treatment followed by long-term antiviral treatment (an additional 3-month course) of oral valacyclovir did not show improvements in neuropsychological testing 12 months later compared to placebo.[87]

Although mosquito bites account for nearly all human cases of WNV, transmissions via blood products, organ transplantation, transplacental transfer, and breast milk have been documented.[16,88] Similar to other arboviruses, the incubation period for WNV ranges from 2 to 14 days, although periods of up to 21 days have been observed in immunocompromised patients. Infection with WNV is asymptomatic in most adults or causes a mild flu-like syndrome characterized by fever, malaise, myalgia, and lymphadenopathy. Among 41,762 reported cases of WNV in the United States between 1999 and 2014, the overall mortality rate was approximately 4% (9% in patients with neuroinvasive disease). In 2020, the CDC reported a total of 557 cases of WNV and 38 deaths. CSF examination of WNV encephalitis typically shows pleocytosis and a slightly elevated CSF protein concentration. Several diagnostic methods have been developed for WNV, including a PCR assay and enzyme-linked immunosorbent assay (ELISA) tests. Treatment is typically supportive, including treatment for seizures and increased ICP, and in the majority of cases, the disease is self-limiting.[88]

CMV has emerged as a major cause of morbidity and mortality in immunocompromised patients, including HIV-infected individuals and transplant recipients on immunosuppressant therapy. CNS infections with CMV are often difficult to treat, with higher failure rates and poor outcomes. Combination therapy with ganciclovir and foscarnet is recommended for induction treatment due to the potential for poor outcomes with monotherapy.[14] In adult patients, ganciclovir 5 mg/kg every 12 hours and foscarnet 60 mg/kg every 8 hours (or 90 mg/kg every 12 hours) for 3 weeks or until symptom resolution are recommended during the induction phase, followed by maintenance phase with either induction agent. Some clinicians may use oral valgancyclovir for maintenance treatment of CMV CNS disease, although the use of this agent is not well established. Other interventions that may improve survival outcomes include the initiation of highly active antiretroviral therapy in untreated HIV-infected patients and reduction of immunosuppression intensity in transplant recipients. Although there is no vaccine for the prevention of CMV disease, there are multiple vaccine candidates in the process for FDA approval.

HIV encephalitis is a common CNS complication associated with AIDS. Frequently, patients may complain of headache, photophobia, or stiff neck at the time of presumed seroconversion. As the disease progresses neurologic symptoms are frequently reported secondary to other opportunistic infections. Diagnosis of viral encephalitis is difficult because mental status and neurologic examinations are not sensitive enough to detect early changes. Direct evidence of HIV encephalitis can be obtained through CSF culture, p24 antigen testing, and qualitative or quantitative PCR for HIV RNA. Diagnostic workup of coinfections, such as HSV, *Toxoplasma gondii, Mycobacterium tuberculosis*, Aspergillus spp., and Cryptococcus spp., should also be performed. See Chapter 148 "Human Immunodeficiency Virus" for a complete discussion of infectious complications in HIV-positive individuals.

CNS INFECTIONS IN SPECIAL POPULATIONS

This section discusses additional pathogens that can cause CNS infections. For discussion on CNS infections caused by Cryptococcus, Histoplasma, and Aspergillus species, the interested reader can refer to Chapter 144, "Invasive Fungal Infections." CNS infection due to *Treponema Pallidum* (neurosyphilis) is discussed in Chapter 140, "Sexually Transmitted Diseases."

Bacillus Species

Bacillus anthracis, the causative agent of anthrax, is a nonmotile spore-forming, gram-positive, rod-shaped bacterium. The disease is common in wild and domestic animals. Biodefense experts place *Bacillus anthracis* at or near the top of the list for potential threat agents. It enters the host in the form of spores at the epidermis (cutaneous anthrax), the gastrointestinal epithelium (gastrointestinal anthrax), or the lung mucosa (inhalation anthrax). Anthrax meningitis has been reported with all three clinical forms of anthrax and likely results from hematogenous spread across the blood–brain barrier, generally presenting as hemorrhagic meningitis. Anthrax meningitis is characterized by a fulminant, rapidly progressive clinical course and is nearly always fatal even with treatment. For diagnosis, blood and CSF exam for Gram stain, culture PCR, and toxin assays are recommended.[89]

For the general adult population, empiric treatment for suspected anthrax meningitis should include ≥3 antimicrobial drugs with activity against *B. anthracis*.[89] At least one antimicrobial agent should have bactericidal activity, ≥1 should be a protein synthesis inhibitor for suppression of exotoxin production, and all should have good CNS penetration. A higher percent survival has been observed for patients with anthrax meningitis receiving 3 antimicrobials than those receiving only 2 antimicrobial agents.[90]

⑤ Empiric regimens that include high doses of intravenous fluoroquinolones (ciprofloxacin preferably, levofloxacin or moxifloxacin) along with a carbapenem (meropenem preferably, doripenem or imipenem/cilastatin) and a protein synthesis inhibitor (eg, linezolid preferred or clindamycin) are recommended for ≥ 2 to 3 weeks until clinical criteria for stability are met. Once penicillin susceptibility is confirmed, the carbapenem can be de-escalated to intravenous penicillin G or ampicillin.[89] In addition, adjunctive corticosteroids should be considered.

Bacillus cereus is an unusual cause of CNS infections in immunocompromised patients. Occasional outbreaks may occur in the nosocomial setting. One such outbreak was discovered in a cluster of five patients with AML. All patients were started on vancomycin at time of neurological symptom onset, which is a treatment of choice with frequent resistance to beta-lactams and less frequent documented resistance to carbapenems.[91]

Borrelia burgdorferi (Lyme Disease)

Lyme disease (LD) is caused by the spirochete *Borrelia burgdorferi* and is the most common tick-borne infection in North America and Europe.[92] Lyme neuroborreliosis (LNB) is an infectious disorder of the nervous system caused by *B. burgdorferi* and has been reported in up to 15% of patients with untreated LD. CNS involvement may include meningitis, myelitis, cerebral vasculitis, or encephalitis. Clinical manifestations include fever, headache, fatigue, photosensitivity, confusion, hemiparesis, cerebellar ataxia, painful radiculitis, cranial palsy, and Parkinson-like symptoms among others. Poliomyelitis-like syndromes and acute stroke-like symptoms caused by cerebral vasculitis have been documented but are considered rare. Unlike the European LD, the North American LD is also characterized by a skin rash called erythema migrans.[92,93] There is no international consensus for the diagnosis of Lyme neuroborreliosis (LNB). Diagnosis is based on the presence of neurological symptoms without other obvious reasons, CSF analysis (lymphocytic pleocytosis, moderately elevated protein, normal glucose), intrathecal *B. burgdorferi* antibody production, blood and CSF serologic testing (ELISA plus Western blot), and MRI demonstrating areas of inflammation.[92-94] PCR testing for detection of *B. burgdorferi* in CSF has a sensitivity of <30% with an unknown specificity; therefore, it is not routinely recommended. Parenteral treatment with ceftriaxone once daily is recommended as first-line treatment of LNB.

⑤Patients with cranial neuropathy without clinical signs of meningitis may be treated with oral amoxicillin, doxycycline, or cefuroxime axetil. European guidelines also recommend oral doxycycline as a first-line option for patients with symptoms confined to the meninges, cranial nerves, nerve roots, or peripheral nerves based on its CSF penetration, ability to achieve CSF concentrations above the MIC, and several studies showing similar short- and long-term efficacy to various parenteral regimens.[93] Alternative parenteral options to ceftriaxone include cefotaxime or penicillin G. For patients intolerant to β-lactams, oral or intravenous doxycycline is suggested.

Mycobacterium tuberculosis

⑤*M. tuberculosis* is the primary cause of tuberculous meningitis and remains the most life-threatening form of extrapulmonary tuberculosis. The incidence of tuberculosis, in general, has decreased to 3 cases per 100,000 individuals in the United States in 2016.[95] The guidelines jointly sponsored by the CDC, IDSA, and the American Thoracic Society recommend an initial regimen of four drugs for empirical treatment of drug-susceptible *M. tuberculosis* in adults. The recommended regimen consists of isoniazid, rifampin, pyrazinamide, and ethambutol for the first 2 months, followed by isoniazid plus rifampin for an additional 7 to 10 months, although the optimal duration has not been defined. Furthermore, initial adjunctive corticosteroid therapy tapered over 6 to 8 weeks is recommended, which provides mortality benefit. The recommended therapy for HIV-positive individuals is similar as that for immunocompetent patients.[95,96] In HIV-infected patients with tuberculous meningitis, antiretroviral therapy should not be initiated in the first 8 weeks of antituberculosis therapy to reduce the risk of immune reconstitution syndrome (IRIS). Therapy should be individualized based on susceptibility patterns and evidence-based guidelines including those by the WHO.[97]

Nocardia

Nocardia is an aerobic, gram-positive bacterium. *Nocardia* species represent a ubiquitous group of environmental bacteria that commonly cause opportunistic infections in immunocompromised individuals. Nevertheless, up to 20% of patients with nocardiosis are apparently healthy, although the presence of nocardiosis might reveal a previously unidentified primary immunodeficiency in immunocompetent patients.[98] Pulmonary nocardiosis is the most common clinical presentation and CNS nocardiosis represents the second most frequently involved organ. The usual presentation of CNS infection is single or multiple brain abscesses. CNS symptoms appear gradually and are nonspecific including headache, nausea, vomiting, seizures, and mental status changes. MRI of the brain is the recommended imaging modality. Specific therapeutic recommendations on the basis of prospective controlled trials for nocardiosis are lacking. In addition, *Nocardia* has inconsistent antimicrobial susceptibility patterns *in vitro*.[99] Thus, the management of nocardiosis must be individualized and isolates should undergo antimicrobial testing for treatment decisions. Surgical management may be necessary in many cases.[100]

⑤According to the 2019 guidelines from the American Society of Transplantation for the treatment of nocardia infections in transplant patients, imipenem/cilastatin coadministered with amikacin alone or in a three-drug regimen with trimethoprim-sulfamethoxazole can be used as empiric therapy for cerebral disease or life-threatening disease. In critically ill patients with significant renal dysfunction where it may be desirable to avoid trimethoprim-sulfamethoxazole and aminoglycosides, treatment with linezolid is an option until susceptibility results are available. Alternative therapies include cefotaxime, ceftriaxone, and minocycline, although some Nocardia species are resistant to these agents, and therefore, use should be guided by susceptibility testing. Nocardiosis appears to be a rare infection in children. Antibiotics reported useful in children are similar to those used in adults. Combined treatment is required until there is evidence of clinical improvement and antimicrobial susceptibility is confirmed. Parenteral therapy is recommended for 3 to 6 weeks followed by appropriate oral therapy for a total of 12 months. After completion of antibiotic therapy, secondary prophylaxis with trimethoprim-sulfamethoxazole can be considered at doses of one double strength tablet daily for adults. However, breakthrough nocardial infections may still occur.[100] Therefore use of trimethoprim-sulfamethoxazole prophylaxis should not prevent clinicians from considering nocardial infections in differential diagnosis. Patients should be monitored for one year after completion of therapy for relapse.

Primary Amoebic Meningoencephalitis (PAM)

Naegleria fowleri is a thermophilic, unicellular parasite that lives in stagnant fresh or brackish waters and causes a rare form of nearly fatal CNS infection known as Primary Amoebic Meningoencephalitis (PAM). Humans acquire PAM when water is insufflated through the nostrils usually while swimming in warm freshwater lakes and rivers. The time from exposure to *N. fowleri* to the onset of symptoms is 1 to 9 days. The pathogen migrates to the brain along the olfactory nerve. Signs and symptoms of PAM include severe frontal headache, fever, nausea, vomiting, seizures, altered mental status, hallucinations, and coma.

Even with early recognition of PAM, progression is rapid and the clinical prognosis is poor. PAM is a rare disease that is almost always fatal. In the United States, there have been 148 PAM infections from 1962 through 2019 with only four survivors. PAM disproportionately affects males and children. Several drug combinations have been used for treatment of PAM.[101] Based on treatment regimens used in survivors, the CDC recommend combination therapy with miltefosine (an oral drug used to treat breast cancer and leishmaniasis), azithromycin, rifampin, fluconazole, and conventional amphotericin B (intravenous and intrathecal) and dexamethasone.

Toxoplasma gondii

⑤ Toxoplasmic encephalitis (TE) is caused by the protozoan *T. gondii*. Approximately 11% of the U.S. population 6 years and older have been infected with *T. gondii*. In other parts of the world, up to 95% of populations are infected. The primary routes of transmission are foodborne, animal-to-human (cats serving as the definitive host), and mother-to-child (congenital).[96,102] TE is typically caused by the reactivation of disease in immunocompromised patients, especially those with AIDS, or intrauterine infection in newborns. Clinical manifestations can range from asymptomatic in healthy, nonpregnant patient to headache, seizures, confusion, hemiparesis, cranial nerve abnormalities, or fever in immunocompromised patients. In congenital toxoplasmosis, patients may also present with hydrocephalus, intracerebral calcification, microcephaly, convulsions, or chorioretinitis.[14,96] Definitive diagnosis of TE requires a clinical sample via a brain biopsy; therefore, TE is presumptively diagnosed on the basis of clinical symptoms, positive serology for antitoxoplasma IgG antibodies, and identification of space-occupying lesions on CT, MRI, or other radiologic imaging. In patients with AIDS, MRI typically shows multiple ring-enhancing lesions.

T. gondii can also be detected by PCR in CSF. However, the sensitivity is low (50%) and the result is usually negative once treatment has started.[96,102] First-line treatment for TE in adults consists of pyrimethamine plus sulfadiazine plus leucovorin. Leucovorin is added to the treatment regimen to reduce the likelihood of hematologic toxicity associated with pyrimethamine. In patients who are unable to tolerate sulfadiazine, due to allergies or impaired renal function, clindamycin may be used as an alternative. Other alternative treatment options are available, including trimethoprim-sulfamethoxazole, but have not been extensively studied. Treatment recommendations are the same in pediatric patients; however, several of the alternative regimens have not been studied in children.[96,102] After completion of initial 6-week therapy, chronic maintenance therapy should be initiated and continued based on risk factors and immune status.

EVALUATION OF THERAPEUTIC OUTCOMES

Because of the potential for rapid deterioration associated with CNS infections, the presence of fever, headache, meningismus (eg, nuchal rigidity, Brudzinski's, or Kernig's sign), and signs of cerebral dysfunction should be evaluated every 4 hours for the initial 3 days and then daily thereafter. The Glasgow Coma Scale should be used in severely ill patients. Trends in improvement and resolution rather than single evaluations in time are more important in monitoring the signs and symptoms of meningitis. Continued therapy should be based on the assessment of clinical improvement, culture, and susceptibility testing results. Once a pathogen is identified, anti-infective therapy should be tailored to the specific pathogen (Tables 128-4 and 128-5). Throughout the course of treatment, efficacy parameters such as signs and symptoms, microbiologic findings, and CSF examination should be followed to evaluate the success of meeting the desired outcomes. If adjunctive dexamethasone is used, careful monitoring of signs and symptoms of gastrointestinal bleeding and hyperglycemia should be employed. Moreover, the use of dexamethasone may interfere with the interpretation of clinical response to treatment, such as resolution of fever.

ABBREVIATIONS

ACIP	Advisory Committee on Immunization Practices
AFB	acid fast bacillus

SELF-ASSESSMENT QUESTIONS

1. Which of the following pathogen is the leading cause of acute bacterial meningitis in adults in the western societies?

   A. *Streptococcus* group B

   B. *Neisseria meningitides*

   C. *Streptococcus pneumoniae*

   D. *Haemophilus influenzae*

2. The following are true regarding initiation of anti-infective therapy in acute CNS infection, except:

   A. Empiric anti-infective therapy should be initiated as soon as possible after a diagnosis is suspected.

   B. Blood samples should be collected before administration of anti-infective agents.

   C. Supportive care including fluids, electrolytes, antipyretics, and antiemetics should also be given during treatment for possible CNS infections.

   D. Corticosteroids should not be initiated until a final diagnosis of meningitis is confirmed.

3. In children <2 years of age and adults >50 years of age, empiric coverage of which of the following pathogen is recommended?

   A. *Listeria monocytogenes*

   B. *Legionella pneumophila*

   C. *Neisseria meningitidis*

   D. *Mycoplasma pneumoniae*

4. Which of the following supportive agent has been associated with increased mortality in patients with bacterial meningitis?

   A. Mannitol

   B. Glycerol

   C. 3% hypertonic saline

   D. Levetiracetam

5. In patients with suspected fungal meningitis, which of the following antifungal agent should be avoided during induction therapy due to poor CSF penetration?

   A. Flucytocine

   B. Itraconazole

   C. Fluconazole

   D. Voriconazole

6. According to the Infectious Diseases Society of America, the recommended treatment regimen for a 40-year-old patient with suspected acute, community-acquired bacterial meningitis consists of:

   A. Cefazolin, vancomycin, and levofloxacin

B. Ceftriaxone and vancomycin

C. Ceftriaxone, ampicillin, and aminoglycoside

D. Ceftriaxone and ampicillin

7. The generally recommended duration of intravenous antibiotic treatment of meningitis caused by *Streptococcus pneumoniaea* is:

   A. 7 days

   B. 10-14 days

   C. 4-6 weeks

   D. 12-18 weeks

8. The main rationale for the inclusion of vancomycin to the empiric regimen of non-healthcare-associated bacterial meningitis is for covering possible resistant:

   A. *Streptococcus pneumoniae*

   B. *Staphylococcus aureus*

   C. *Enterococcus facium*

   D. *Listeria monocytogenes*

9. Which of the following antipseudomonal agent is not included in the recommended regimen for the treatment of healthcare-associated meningitis and ventriculitis?

   A. Meropenem

   B. Piperacillin-tazobactam

   C. Cefepime

   D. Ceftazidime

10. Adjunctive use of corticosteroids would be indicated for:

   A. Brain abscess with significant edema

   B. Meningitis due to *Haemophilus influenzae* in children

   C. Meningitis due to *Streptococcus pneumoniae* in adults

   D. Meningitis due to *Mycobacterium tuberculosis*

   E. All of the above

11. Which of the following is NOT one of the most common causes of viral encephalitis in the United States?

   A. Arbovirus

   B. Herpes simplex virus

   C. Zika virus

D. Enterovirus

12. For the treatment of CNS infection due to inhaled *Bacillus anthracis,* CDC recommended:

    A. ≥3 antibiotics with activity against *Bacillus anthracis*

    B. Anthrax Vaccine Adsorbed

    C. Antitoxin (raxibacumab or AIGIV)

    D. All of the above

13. According to CDC, the recommended total duration of treatment of Primary Amoebic Meningoencephalitis (PAM) due to *Naegleria fowleri* is:

    A. 7 days

    B. 14 days

    C. 28 days

    D. 3 months

14. The recommended treatment regimen of brain abscess due to *Nocardia* may include the following, except:

    A. Surgical resection of abscess

    B. Ceftriaxone as the core antibiotic agent

    C. Combination including trimethoprim-sulfamethoxazole and imipenem

    D. At least 12 months duration

15. Which of the following is true of *Toxoplasma* encephalitis and its treatment?

    A. *Toxoplasma gondii* is transmitted when water is insufflated through the nostrils usually while swimming in warm freshwater lakes and rivers.

    B. It is least common in immunocompromised individuals.

    C. *Toxoplasma* encephalitis is diagnosed using CSF PCR, which has a sensitivity of 99%.

    D. Treatment includes a combination of pyrimethamine, sulfadiazine, and leucovorin.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** Streptococcus pneumoniae is the leading cause of acute bacterial meningitis in adults in the western societies. *Neisseria meningitidis* and *Haemophilus influenzae* type b have also been important causes of acute bacterial meningitis but their incidence has decreased substantially over time mainly due to introduction of effective vaccinations. See the “Etiology” section for more information.

2. **D.** Acute CNS infections are a medical emergency and should be treated as such. Blood and CSF samples are useful for pathogen identification and optimization of anti-infective treatment, though sample collection should not delay the administration of anti-infective agents. The European guidelines for acute bacterial meningitis recommend that antibiotics should be administered within an hour from when meningitis is suspected. The IDSA recommends corticosteroids be administered 10 to 20 minutes prior to or concomitant with the first dose of antibiotics. See the “General Approach to Treatment, Nonpharmacologic and Supportive Therapy” and “Dexamethasone as an Adjunctive Treatment for Acute Bacterial Meningitis” sections for more information.

3. **A.** Meningitis due to *L. monocytogenes* primarily affects neonates, alcoholic or immunocompromised individuals (including pregnant women), and

the elderly. See the “*Listeria monocytogenes*” section for more information.

4. **B.** Glycerol should be avoided as a supportive care agent in acute bacterial meningitis because it has been associated with a higher mortality rate. See the “General Approach to Treatment, Nonpharmacologic and Supportive Therapy” section for more information.

5. **B.** Itraconazole has poor penetration into the CSF. Refer to Table 128-3 for more information on the penetration of anti-infective agents into the CSF.

6. **B.** The Infectious Diseases Society of America recommends vancomycin plus a third-generation cephalosporin as empiric therapy for suspected acute, community-acquired bacterial meningitis in patients 2 to 50 years old. Refer to Table 128-2 for more information on empiric antimicrobial regimens.

7. **B.** The duration of treatment for bacterial meningitis is often based on causative agent. For bacterial meningitis caused by *Streptococcus pneumoniaea*, the Infectious Diseases Society of America recommends 10 to 14 days of therapy. See Table 128-4 for more information on the duration of antibiotic treatment.

8. **A.** The Infectious Diseases Society of America recommends the addition of vancomycin to ceftriaxone for coverage of potentially cephalosporin-resistant *Streptococcus pneumoniae* isolates in acute, community-acquired, bacterial meningitis. Refer to the “*Streptococcus pneumoniae*” section for more information.

9. **B.** Piperacillin-tazobactam is not included in the recommended regimen for the treatment of healthcare-associated meningitis and ventriculitis because tazobactam does not penetrate the blood−brain barrier (Table 128-3).

10. **E.** Adjunctive use of corticosteroids are indicated for meningitis due to *Haemophilus influenzae* (children), *Streptococcus pneumoniae* (adults), *Mycobacterium tuberculosis*, and brain abscess with significant edema. See “*Haemophilus influenza type b*,” “*Streptococcus pneumoniae*,” “*Bacterial Brain Abscess*,” and “*Mycobacterium Tuberculosis*” sections for more information.

11. **C.** Although Zika virus has been shown to cause encephalitis and congenital brain developmental disorders, it is not a common cause of encephalitis in the United States. There have been no confirmed cases of Zika virus disease in the United States. See the “*Viral Encephalitis”* section for more information.

12. **D.** The Centers for Disease Control and Prevention recommends ≥3 antibiotics with activity against *Bacillus anthracis*, a three-dose subcutaneous series of Anthrax Vaccine Adsorbed, and an antitoxin for the treatment of CNS infection due to inhaled *Bacillus anthracis*. Refer to the “*Bacillus anthracis*” section for more information.

13. **C.** According to the Centers for Disease Control and Prevention, the recommended treatment duration of Primary Amoebic Meningoencephalitis (PAM) due to *Naegleria fowleri* is 28 days. See the “Primary Amoebic Meningoencephalitis (PAM)” section for more information.

14. **B.** Trimethoprim-sulfamethoxazole is active against most *Nocardia* species and is commonly the core antibiotic used for the treatment of CNS infections. It is used in combination with imipenem or ceftriaxone and, in severe diseases, with a third agent such as linezolid. See the “*Nocardia*” section for more information.

15. **D.** *T. gondii* is transmitted primarily via foodborne, animal-to-human, and mother-to-child routes, and most commonly caused by the reactivation of disease in immunocompromised hosts. Definitive diagnosis of TE requires a clinical sample via a brain biopsy; however, *T. gondii* can also be detected by PCR in CSF, but the sensitivity is low (50%). Refer to the “*Toxoplasma gondii*” section.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter 129: Lower Respiratory Tract Infections

Evan J. Zasowski; Martha Blackford

KEY CONCEPTS

KEY CONCEPTS

① Respiratory infections remain a major cause of morbidity from acute illness in the United States and represent the most common reasons why patients seek medical attention.

② The majority of pulmonary infections follow colonization of the upper respiratory tract with potential pathogens, whereas microbes less commonly gain access to the lungs via the bloodstream from an extrapulmonary source or by inhalation of infected aerosol particles. The competency of a patient's immune status is an important factor influencing the susceptibility to infection, etiologic cause, and disease severity.

③ An appropriate treatment regimen for a patient with uncomplicated lower respiratory tract infection can be established by evaluating the patient history, physical examination, chest radiograph, and properly collected sputum for culture interpreted in light of current knowledge of the most common lung pathogens and their antibiotic susceptibility patterns within the community.

④ Acute bronchitis is most commonly caused by respiratory viruses and is almost always self-limiting. Therapy targets associated symptoms such as lethargy, malaise, or fever and may include fluids for rehydration. Routine use of antibiotics should be avoided and medication to suppress cough is rarely indicated.

⑤ Chronic bronchitis is caused by several interacting factors, including inhalation of noxious agents (most prominent are cigarette smoke and exposure to occupational dusts, fumes, and environmental pollution) and host factors including genetic factors and bacterial (and possibly viral) infections. The hallmark of this disease is a chronic cough, accompanied by excessive production, and expectoration of sputum with a persistent presence of microorganisms in the patient's sputum.

⑥ Treatment of acute exacerbations of chronic bronchitis includes attempts to mobilize and enhance sputum expectoration (chest physiotherapy, humidification of inspired air), oxygen if needed, aerosolized bronchodilators in select patients with demonstrated benefit, and possibly antibiotics.

⑦ Respiratory syncytial virus is the most common cause of acute bronchiolitis, an infection that mostly affects infants during their first year of life. In the well infant, bronchiolitis usually is a self-limiting viral illness.

⑧ The most prominent pathogen causing community-acquired bacterial pneumonia in otherwise healthy adults is *Streptococcus pneumoniae*, whereas the most common pathogens causing hospital-acquired pneumonia are *Staphylococcus aureus* and gram-negative aerobic bacilli.

⑨ Empiric antimicrobial therapy for pneumonia should consist of antibiotic regimens targeting presumed causative pathogens based on clinical presentation and patient-specific characteristics, local epidemiology, and resistance patterns.

⑩ Microbiologic tests for pneumonia etiology should be performed when clinically indicated and used along with patient clinical response to tailor antibiotic therapy using evidence-based pathogen-directed therapy when possible.

BEYOND THE BOOK

BEYOND THE BOOK

Create a study chart of the following antibiotics with potential utility in lower respiratory tract infections: ceftazidime-avibactam; ceftolozane-tazobactam; meropenem-vaborbactam; cefiderocol, imipenem-relabactam, plazomicin, eravacycline. On the chart include spectrum of activity, pharmacokinetics (ADME), dosing (including need for adjustment in special populations), adverse effects, Food and Drug Administration (FDA)-approved indication(s), level of evidence supporting use in lower respiratory tract infections (none, in vitro/in vivo, case report/series, observational study, randomized controlled trial), and potential place in therapy of lower respiratory tract infections.

INTRODUCTION

① Respiratory tract infections remain a major cause of morbidity from acute illness in the United States and most likely represent the single most common reason patients seek medical attention. This chapter focuses on bacterial and viral infections involving the lower respiratory tract, which includes the tracheobronchial tree and lung parenchyma.

② The respiratory tract has an elaborate system of host defenses, including humoral immunity, cellular immunity, and anatomic mechanisms.[1] When functioning properly, respiratory tract host defenses are markedly effective in protecting against pathogen invasion and removing potentially infectious agents from the lungs. For the most part, infections in the lower respiratory tract occur only when these defense mechanisms are impaired, as in cases of dysgammaglobulinemia or compromised ciliary function, such as that caused by the chronic inflammation accompanying cigarette smoking. In addition, local defenses may be overwhelmed when a particularly virulent microorganism or excessive inoculum invades lung parenchyma. Most pulmonary infections follow colonization of the upper respiratory tract with potential pathogens, which, after achieving sufficiently high concentrations, gain access to the lung via aspiration of oropharyngeal secretions. Less commonly, microbes enter the lung via the blood from an extrapulmonary source or by inhalation of infected aerosolized particles. The specific type of pulmonary infection caused by an invading microorganism is determined by a variety of host factors, including age, anatomic features of the airway, and specific characteristics of the infecting agent.

The most common infections involving the lower respiratory tract are bronchitis, bronchiolitis, and pneumonia. Bronchitis and bronchiolitis are inflammatory conditions of the large and small airways, respectively, of the tracheobronchial tree. The inflammatory process does not extend to the alveoli. Bronchitis frequently is classified as acute or chronic; acute bronchitis occurs in individuals of all ages, whereas chronic bronchitis primarily affects adults. Bronchiolitis is a disease of infancy.

Lower respiratory tract infections in children and adults most commonly result from either viral or bacterial invasion of lung parenchyma. The diagnosis of viral infections rests primarily on the recognition of a characteristic constellation of clinical signs and symptoms. Because treatment of viral respiratory infections is largely supportive, only occasionally does the diagnosis require laboratory confirmation; this is achieved through serologic tests or identification of the organism by culture or antigen detection in respiratory secretions.[2] Laboratory techniques using polymerase chain reaction (PCR), microarrays, and multiplex ligation-dependent probe amplification, to name a few, have emerged to identify specific pathogens rapidly and accurately.[3]

In contrast, because bacterial pneumonia usually necessitates expedient, effective, and specific antibiotic therapy, its management depends, in large part, on an understanding of the risk factors for acquiring pneumonia, predominant pathogens within the community, and, if necessary, isolation of the etiologic agent by culture from lung tissue or secretions.[4-6] The pharynx is colonized with many organisms that can cause pneumonia; therefore, culture of expectorated sputum can be misleading unless the specimen is examined to ensure that it has originated from the lower respiratory tract. The Gram stain provides the easiest method for distinguishing lower from upper respiratory tract secretions; moreover, through determination of the shape and color of the bacteria, the Gram stain frequently narrows the microbiologic differential diagnosis sufficiently to allow accurate initial therapy. Scanned under low-power microscopy, Gram-stained expectorated upper respiratory tract secretions contain many irregularly shaped epithelial cells with little evidence of inflammation and may not reflect the pathogen. In contrast, a lower-tract specimen from a patient with bacterial pneumonia usually contains multiple neutrophils per high-powered field and a single or predominant bacterial species. More aggressive procedures can be performed to more accurately identify responsible pathogens including respiratory secretion samples obtained via bronchoscopy or bronchoalveolar lavage (BAL). Culture of specimens confirmed to originate from the lower tract by Gram stain or collection via BAL provides valuable diagnostic information for the majority of patients with bacterial pneumonia. In addition, pneumonia promotes the release of inflammatory mediators and acute-phase proteins, such as C-reactive protein, which can be significantly elevated in serum in the presence of respiratory tract infections.[7] Unfortunately except for pathogen identification by culture, elevations in C-reactive protein, changes in sputum color or peripheral white blood count, etc., are not specific for determining viral, bacterial, or fungal etiology. Newer genomic testing may aid tremendously in determining the identity of responsible pathogen(s) and then selection of optimal antimicrobial therapy.

③ An appropriate treatment regimen for the patient with an uncomplicated lower respiratory tract infection usually can be established by history, physical examination, chest radiograph, and properly collected sputum cultures interpreted in light of the most common lung pathogens and their antibiotic susceptibility patterns within the community.[2,5] More sophisticated or invasive diagnostic methods (eg, computed tomography, bronchoscopy, and lung biopsy) are reserved for severely ill patients who are unable to expectorate sputum or who are not responding to empirical therapy or for pulmonary infections occurring in immunocompromised patients.[2]

BRONCHITIS

Acute Bronchitis

Epidemiology and Etiology

Acute bronchitis occurs year-round, but more commonly during the winter months. Cough accounts for more than 6 million ambulatory visits annually, underscoring its major financial impact on the healthcare system.[8] Acute bronchitis is characterized by inflammation of the epithelium of the large airways resulting from infection or exposure to irritating environmental triggers (eg, air pollution and cigarette smoke). Acute (viral) infection and/or smoking are the most common precipitants of attacks, which usually manifest initially as a persistent cough.

④ Respiratory viruses are the predominant infectious agents associated with acute bronchitis, accounting for 85% to 95% of occurrences. The most common infecting agents include influenza A and B, respiratory syncytial virus (RSV), and parainfluenza virus, whereas the common cold viruses (rhinovirus and coronavirus) and adenovirus are encountered less frequently. Although far less common, bacterial pathogens are involved in a minority of cases and involve pathogens often associated with community-acquired pneumonia (CAP) including *Mycoplasma pneumoniae*, *Streptococcus pneumonia, Haemophilus influenzae, Moraxella catarrhalis*, and less commonly *Chlamydophila pneumoniae* and *Bordetella pertussis*, the agent responsible for whooping cough. Although a primary bacterial etiology for acute bronchitis appears rare, secondary bacterial infection may be involved, particularly in patients with underlying disease(s).[8]

Pathogenesis

④ Since acute bronchitis is primarily a self-limiting illness and rarely a cause of death, few data describing the pathology are available. In general, infection of the trachea and bronchi yields inflammation-induced hyperemic and edematous mucous membranes with an increase in bronchial secretions. Destruction of respiratory epithelium can range from mild to extensive and may affect bronchial mucociliary function. In addition, the increase in desquamated epithelial cells and bronchial secretions, which can become thick and tenacious, further impairs mucociliary activity. The probability of permanent damage to the airways as a result of acute bronchitis remains unclear but appears unlikely. However, epidemiologic evaluations support the belief that recurrent acute respiratory infections may be associated with increased airway hyperreactivity and possibly the pathogenesis of asthma, chronic obstructive pulmonary disease (COPD), or possibly the asthma-COPD syndrome.[9,10]

Clinical Presentation

Acute bronchitis usually begins as an upper respiratory infection with nonspecific complaints.[8,11] Cough is the hallmark of acute bronchitis and occurs early. The onset of cough may be insidious or abrupt, and the symptoms persist despite resolution of nasal or nasopharyngeal complaints; cough may persist for up to 3 or more weeks. Frequently, the cough initially is nonproductive, but then progresses, yielding mucopurulent sputum. In older children and adults, the sputum is raised and expectorated; in the young child, sputum often is swallowed and can result in gagging and vomiting. Substantial discomfort may result from the coughing. Dyspnea, cyanosis, or signs of airway obstruction are observed rarely unless the patient has underlying pulmonary disease, such as emphysema or COPD. Fever, when present, rarely exceeds 39°C (102.2°F) and appears most commonly with adenovirus, influenza virus, and *M. pneumoniae* infections. The diagnosis typically is made on the basis of a characteristic history and physical examination and should be differentiated from asthma or bronchiolitis as these latter diseases are usually associated with wheezing, shortness of breath, and hypoxemia. Bacterial cultures of expectorated sputum are of limited use because of the inability to avoid normal nasopharyngeal flora by the sampling technique. Similarly, viral cultures are unnecessary. In the absence of important risk factors, including COPD, congestive heart failure, or immune compromise, throat/sputum cultures have no role in the routine care of patients with acute bronchitis. For the vast majority of affected patients, an etiologic diagnosis is unnecessary and will not change the prescribing of routine supportive care for the management of these patients.

Treatment

Desired Outcome

In the absence of a complicating bacterial superinfection, acute bronchitis almost always is self-limiting. The goals of therapy are to provide comfort to the patient and, in the unusually severe case, to treat associated dehydration and respiratory compromise.[8]

General Approach to Treatment

④ Treatment of acute bronchitis is symptomatic and supportive in nature. Reassurance and antipyretics frequently are all that are needed. Bedrest for comfort may be instituted as desired. Patients should be encouraged to drink fluids to prevent dehydration and possibly to decrease the viscosity of respiratory secretions. Mist therapy (use of a vaporizer) may promote the thinning and loosening of respiratory secretions.

Pharmacologic Therapy

Mild analgesic–antipyretic therapy often is helpful in relieving the associated lethargy, malaise, and fever. Aspirin or acetaminophen (650 mg/dose in adults [maximum less than 4 g/day] or 10-15 mg/kg/dose in children [maximum 60-75 mg/kg/day or 5 doses/day]) administered every 4 to 6 hours or ibuprofen (200-800 mg/dose in adults [maximum 3.2 g/day] or 10 mg/kg/dose in children [maximum 40 mg/kg/day]) should be administered every 6 to 8 hours. Aspirin should be avoided in children less than 19 years of age with a fever-causing illness and acetaminophen or ibuprofen used as the preferred agents because of a possible, but unclear and unproven association between aspirin use and the possible development of Reye's syndrome.

Patients may present with mild-to-moderate wheezing. In otherwise healthy patients, no meaningful benefits have been described with the routine use of oral or aerosolized β_2-receptor agonists[11,12] and/or oral or aerosolized corticosteroids. Corticosteroids should be avoided in patients with acute bronchitis. There is no evidence to support the routine use of β_2-receptor agonists in either pediatric or adult patients with acute bronchitis; however, adults with airflow obstruction may have a trend toward improvement in cough.[13] Some clinicians, despite no data, may initiate a brief trial (eg, about 5-7 days) of β_2-receptor agonists and even oral or inhaled corticosteroid for patients with a persistent (more than 14-20 days), troublesome cough. This is rarely, if ever, necessary in patients with uncomplicated acute bronchitis and should be avoided. Cough may persist for 3+ weeks and airway hyperresponsiveness for 5 to 6 weeks in as many as 50% of affected patients. In contrast, COPD patients experiencing an acute exacerbation can benefit from a short course of corticosteroid.

Patients suffering from acute bronchitis frequently medicate themselves with nonprescription cough and cold remedies containing various combinations of antihistamines, sympathomimetics, and antitussives despite the lack of definitive evidence supporting their effectiveness.[8,11] The tendency of these agents to dehydrate bronchial secretions could aggravate and prolong the recovery process. Although not recommended for routine use, persistent, mild cough, which may be bothersome, can be treated with dextromethorphan; more severe coughs may require intermittent codeine or other similar agents.[14] In severe cases, the cough may be persistent enough to disrupt sleep, and use of a mild sedative-hypnotic, concomitantly with a cough suppressant (eg, codeine), may be desirable. However, antitussives should be used cautiously when the cough is productive, and codeine is no longer recommended for use in pediatric patients. The primary or supplemental use of expectorants is questionable because their clinical effectiveness has not been well established.[8]

Routine use of antibiotics for treatment of acute bronchitis should be strongly discouraged due to limited benefit.[8,11,15] In previously healthy patients who exhibit persistent fever or respiratory symptoms for more than 5 to 7 days or for predisposed patients (eg, elderly/frail, COPD, and immune compromised), the possibility of a concurrent bacterial infection should be suspected. When possible, antibiotic therapy should be directed toward anticipated respiratory pathogen(s) (eg, *S. pneumoniae* and *H. influenzae*). *M. pneumoniae*, if suspected by history or if confirmed by culture serology or PCR, can be treated with azithromycin. Alternatively, a fluoroquinolone antibiotic with activity against these suspected pathogens (eg, levofloxacin or moxifloxacin) can be used empirically, but due to the increasing rate of pathogen resistance to current antimicrobial drugs, the use of antibiotics in patients with acute bronchitis should be reserved for only those patients not responding adequately to supportive care and deemed at risk of associated complications. During known epidemics involving the influenza A virus, amantadine or rimantadine may have been effective in minimizing associated symptoms if administered early in the course of the disease; however, treatment with these adamantanes is no longer recommended by the Centers for Disease Control and Prevention (CDC) due to increasing influenza resistance and associated adverse effects (see Chapter 131, “Influenza”). The neuraminidase inhibitors (eg, zanamivir and oseltamivir) and the endonuclease inhibitor baloxavir are active against both influenza A and B viral infections and may reduce the severity and duration of the influenza episode if administered promptly during the onset of the viral infection and are the preferred treatment (see Chapter 131).[12,16] Unfortunately, the incidence of influenza virus resistance to available antiviral drugs is increasing, necessitating reconsideration of how we administer antiviral drugs for prophylaxis and treatment.[12] The concept of antiviral drug combinations has emerged as a successful approach to effectively treat systemic viral infections.[17]

Chronic Bronchitis

Epidemiology and Etiology

Chronic bronchitis, most often a component of COPD, is a clinical diagnosis for a nonspecific, heterogenic disease that primarily affects adults. An in-depth presentation of the spectrum and management of COPD is given in Chapter 45, “Chronic Obstructive Pulmonary Disease”; this section focuses solely on chronic bronchitis. In developed countries, the prevalence of chronic bronchitis is slightly higher in men than in women. Depending on the definition used for chronic bronchitis, 3.4% to 22% of adults have chronic bronchitis and 14% to 74% of COPD patients suffer from chronic bronchitis.[18]

⑤ Chronic bronchitis is defined as the presence of a chronic cough productive of sputum lasting more than 3 consecutive months of the year for 2 consecutive years without an underlying etiology of bronchiectasis or tuberculosis. The disease is a result of several contributing factors; the most prominent factor is cigarette smoking; however, in nonsmokers who develop chronic bronchitis (4%-22%), other factors may be exposure to occupational dusts, fumes, and environmental pollution, and host factors (eg, genetic factors and bacterial [and possibly viral] infections).[18] The contribution of each of these factors and of others (either alone or in combination) to chronic bronchitis is unknown.[19] Cigarette smoke is a well-known airway irritant and is a predominant factor in the etiology of chronic bronchitis. Although previously assumed the most common etiologic cause of chronic bronchitis, more strict prohibition of public smoking and the resultant decrease in chronic tobacco smokers, particularly in developed countries, underscores the importance of other factors as causes of this chronic disease. Airway irritants including occupational dust, chemicals, or air pollution, either alone or more likely in combination, are also responsible for the pathogenesis of chronic bronchitis and may explain the development in nonsmokers.[18] Furthermore, genomic studies have begun to expand our understanding of the molecular pathways that may have clinical relevance in this heterogeneous disease. Lastly, the influence of recurrent respiratory tract infections during childhood or young adult life on the later development of chronic bronchitis remains obscure, but recurrent respiratory infections may predispose individuals to the development of chronic bronchitis. Whether these recurrent respiratory tract infections are a result of unrecognized anatomic abnormalities of the airways or impaired pulmonary defense mechanisms is unclear.

Chronic bronchitis and emphysema are the two main components of COPD/chronic obstructive lung disease.[20-22] The Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines document does not distinguish these two diagnoses (eg, emphysema or chronic bronchitis) in the definition of COPD, but it does define COPD as a disease characterized by airflow obstruction that is not fully reversible and progressive. The GOLD guidelines provide a COPD classification scoring system according to severity that can be helpful in staging patients for intensity of therapy, acute/chronic therapy, and prognosis. Unfortunately, differences in definitions between authoritative organizations may cause confusion in the assignment of patients in clinical trials and thus in assessment and application of study results to clinical care.

Pathogenesis

Chronic inhalation of an irritating noxious substance compromises the normal secretory and mucociliary function of bronchial mucosa.[18] Bronchial biopsy specimens in bronchitic patients underscore the importance of T-cell-derived proinflammatory cytokines (eg, interleukins IL-4, IL-5, IL-13, and interferon gamma) in the pathogenesis and propagation of the observed inflammatory changes. In chronic bronchitis, the bronchial wall is thickened, and the number of mucus-secreting goblet cells on the surface epithelium of both larger and smaller bronchi is increased markedly. In contrast, goblet cells generally are absent from the smaller bronchi of normal individuals. In addition to the increased number of goblet cells, hypertrophy of the mucous glands and dilation of the mucous gland ducts are observed. As a result of these changes, chronic bronchitis has substantially more mucus in the peripheral airways, further impairing normal lung defenses. This increased quantity (overproduction and hypersecretion) of tenacious secretions within the bronchial tree frequently causes mucous plugging of the smaller airways. Accompanying these changes is squamous cell metaplasia of the surface epithelium, edema, and increased vascularity of the basement membrane of larger airways and variable chronic inflammatory cell infiltration. In addition, the amounts of several proteases derived from inflammatory cells are increased and due to COPD-induced defective antiproteases lead to continued destruction of connective tissue. Continued progression of this pathology can result in residual scarring of small bronchi and peribronchial fibrosis augmenting airway obstruction and weakening of bronchial walls.[18]

Clinical Presentation

⑤ The hallmark of chronic bronchitis is a cough that may range from a mild to a severe and incessant coughing productive of purulent sputum. Coughing may be precipitated by multiple stimuli, including simple, normal conversation. Expectoration of the largest quantity of sputum usually occurs on arising in the morning, although many patients expectorate sputum throughout the day. The expectorated sputum usually is tenacious and can vary in color from white to yellow-green. Patients with chronic bronchitis often expectorate as much as 100 mL/day more than normal. As a result, many patients complain of a frequent bad taste in their mouth and of halitosis. Sputum color provides no prognostic indication of infection or cause of an infectious disease exacerbation, that is, viral versus bacterial cause. Although sputum color of more green and yellow can be a predictor of potentially pathogenic bacteria, this is unreliable clinically.[23] The diagnosis of an acute exacerbation requires consideration of a number of different factors all occurring within a discrete timeframe (eg, increased/worsening respiratory symptoms including dyspnea, sputum volume and/or clearance, and cough). The tracking of the number of acute exacerbations and their consequences (decline in forced expiratory volume in 1 second [FEV1]), persistent/worsening of symptoms annually, is extremely important for prognostication and defining ongoing treatment strategies. Each acute exacerbation of chronic bronchitis results in continual declines in lung function.

The diagnosis of chronic bronchitis is based primarily on clinical assessment and history. Any patient who reports coughing sputum on most days for at least 3 consecutive months each year for 2 consecutive years presumptively has chronic bronchitis.[18] The diagnosis of chronic bronchitis is made only when the possibilities of bronchiectasis, cardiac failure, cystic fibrosis, and lung carcinoma, among others, have been effectively excluded. To be more specific in the diagnosis, some investigators have added the criteria of lost wages for 3 or more weeks. In addition, many clinicians attempt to subdivide their patients based on severity of disease to guide therapeutic interventions. Two primary classification proposals are most often used in an attempt to determine the severity of the underlying disease as well as the occurrence/impending occurrence of an acute exacerbation of chronic bronchitis; for disease severity and acute exacerbations the prognostic tools advocated by GOLD are very helpful including classification based on spirometry (“mild” postbronchodilator FEV1 greater than or equal to 80% predicted to “very severe” postbronchodilator FEV1 less than 30% predicted: see Chapter e43, “Evaluation of Pulmonary Function”); the COPD assessment test (eight-item measure of health status), the Clinical COPD Questionnaire (a measure of clinical control), and the Modified Medical Research Council Questionnaire to predict future mortality. The other simple classification system is that proposed by Anthonisen and colleagues in 1987 that is still used to categorize patients in many therapeutic clinical trials.[24] The use of patient symptom diaries can also be helpful in compliant patients. The importance of accurate classification for grouping patients of similar disease involvement cannot be overemphasized with respect to assessing publications outlining treatment strategies for these patients. These classifications attempt to capture specific phenotypes of chronic bronchitis patients. The typical clinical presentation of chronic bronchitis is listed in Table 129-1. Comparison of the trends in changes in a patient’s physical activity, symptoms, and clinical/physical findings from the patient’s “routine” is extremely helpful in determining the presence and severity of an acute exacerbation.

TABLE 129-1

Clinical Presentation of Chronic Bronchitis

Signs and symptoms

- Excessive sputum expectoration
- Cough
- Cyanosis (advanced disease)

Physical examination

- Chest auscultation usually reveals inspiratory and expiratory rales, rhonchi, and mild wheezing with an expiratory phase that is frequently prolonged
- Hyperresonance on percussion with obliteration of the area of cardiac dullness
- Normal vesicular breathing sounds are diminished
- Clubbing of digits (advanced disease)
- Obesity

Chest radiograph

- Increase in anteroposterior diameter of the thoracic cage (barrel chest)
- Depressed diaphragm with limited mobility

Laboratory tests

- Erythrocytosis (advanced disease), that is, increased hematocrit

Pulmonary function tests

- Decreased vital capacity
- Prolonged expiratory flow

In more advanced stages of chronic bronchitis, physical findings associated with cor pulmonale, including cardiac enlargement, hepatomegaly, and edema of the lower extremities, are observed. In general, people with chronic bronchitis tend to maintain at least normal body weight and commonly are obese. Radiographic studies are of limited value in either the diagnosis or follow-up of a patient. The microscopic and laboratory assessments of sputum are used in the overall evaluation of patients with chronic bronchitis. Gram staining of the sputum often reveals a mixture of both gram-positive and gram-negative bacteria, reflecting normal oropharyngeal flora and chronic tracheal colonization (in order of frequency) by non-typable *H. influenzae*, *S. pneumoniae*, and *M. catarrhalis*. Table 129-2 lists the most common bacterial isolates identified from sputum culture for patients experiencing an acute exacerbation of chronic bronchitis. For patients with more severe airflow disease (eg, FEV_1 less than 40% predicted), enteric gram-negative bacilli, *Escherichia coli*, *Klebsiella* species, *Enterobacter* species, and *Pseudomonas aeruginosa* may be significant pathogens during acute exacerbations.

TABLE 129-2

Common Bacterial Pathogens Isolated from Sputum of Patients with Acute Exacerbation of Chronic Bronchitis

Pathogen	Percent of Cultures
H. influenzae[a,b]	45
M. catarrhalis[a]	30
S. pneumoniae[c]	20
E. coli, *Enterobacter* species, *Klebsiella* species, *P. aeruginosa*	5

[a] Often β-lactamase positive.

[b] Vast majority are nontypable strains.

[c] More than 25% of strains may have intermediate or high resistance to penicillin.

Treatment

Desired Outcome

The goals of therapy for chronic bronchitis are twofold: to reduce the severity of chronic symptoms and to ameliorate acute exacerbations and achieve prolonged exacerbation-free intervals.

General Approach to Treatment

The approach to treatment of chronic bronchitis is multifactorial.[18] First and foremost, attempts must be made to reduce the patient's exposure to known bronchial irritants (eg, smoking and workplace pollution). A complete occupational and environmental history for determination of exposure to noxious, irritating gases as well as preference toward cigarette smoking must be assessed. Often easier to discuss than accomplish, reasonable attempts should be made with the patient to reduce or eliminate the number of cigarettes smoked daily and to reduce exposure to secondhand smoke. An organized, coordinated, smoking cessation program, including counseling, possibly hypnotherapy, and the adjunctive use of nicotine substitutes (eg, nicotine gum or patch) or other pharmacotherapy (eg, bupropion and varenicline), may promote the reduction or complete withdrawal from cigarette smoking. Often just as difficult is modification of exposure to irritating substances within the home and workplace.

The importance of pulmonary rehabilitation has been realized in improving the quality of life for patients with chronic respiratory diseases.[25] Pulmonary rehabilitation is broadly defined as an interdisciplinary program individualized for patients with chronic respiratory impairment designed to optimize each patient's physical and social performance and autonomy. A personalized exercise-training program including resistance and aerobic exercise is central to these programs. Pulmonary rehabilitation programs relieve dyspnea and fatigue, improve a patient's emotional function, and enhance their sense of control over their disease and life. These improvements are often moderately large and clinically relevant.[25] The challenge for the future is to determine what components of a comprehensive pulmonary rehabilitation program provide the greatest benefit.

⑥ Measures to provide chest physiotherapy (eg, pulmonary "toilet") can be instituted.[26] Clearly the cost-effectiveness of chest physiotherapy needs to be better described but their short-term effects have been demonstrated and may be of symptomatic value to many patients experiencing an acute exacerbation of the chronic bronchitis. During acute pulmonary exacerbations of the disease, the patient's ability to mobilize and expectorate sputum may be reduced dramatically. In these instances, attempts at postural drainage techniques, with instruction and or active participation from a respiratory therapist, may assist in promoting clearance of pulmonary secretions. In addition, humidification of inspired air may promote the hydration (liquefaction) of tenacious secretions, allowing for removal that is more productive. Use of aerosolized mucolytic aerosols, such as *N*-acetylcysteine (NAC) and DNAse, is of questionable therapeutic value, particularly considering their propensity to induce bronchospasm (NAC) and their excessive cost. NAC cleaves the disulfide bonds of mucus, decreasing its elastic property that is important for upward mobility and then expectoration. Aerosol mucolytic therapy was associated with a small reduction in acute exacerbations in subjects with chronic bronchitis or COPD and did not cause any harm, improve quality of life, or slow the decline of lung function.[27] The clinical benefit may be greater for chronic bronchitis/COPD patients who have frequent or prolonged exacerbations and are unable to utilize inhaled corticosteroids or long-acting β_2-agonists.[27] Although limited data are available, chronic use of oral or aerosolized bronchodilators may be of benefit by increasing mucociliary and cough clearance. For patients with moderate to severe COPD, combination therapy with a long-acting β_2-agonist and inhaled corticosteroid led to decreased exacerbations and rescue medication use, while it also improved quality of life, lung function, and symptom scores compared with long-acting β_2-agonist monotherapy.

Pharmacologic Therapy

Patients should be up to date with vaccinations, particularly pneumococcal and an annual influenza vaccine. For patients who consistently demonstrate clinical limitation in airflow, a therapeutic challenge of a short-acting β_2-agonist bronchodilator (eg, as albuterol aerosol) could be considered; however, there is insufficient evidence to recommend the routine use of pharmaceutical agents for cough relief.[18] Pulmonary function tests should be performed before and after β_2-agonist aerosol administration for more objective determination of a patient's propensity to benefit from supplemental aerosol therapy. Regular use of a long-acting β-receptor agonist aerosol (eg, salmeterol and formoterol) in responsive patients is more effective and probably more convenient than short-acting β_2-receptor agonists.[28] The aerosol route for β_2-receptor agonist and/or corticosteroid administration is favored over systemic formulations for improved patient acceptance and compliance and to minimize the number and magnitude of associated adverse effects. Chronic inhalation of a combination long-acting β-receptor agonist (LABA) and a corticosteroid (eg, salmeterol-fluticasone and formoterol-mometasone) improved pulmonary function and quality of life.[29] Long-term use of aerosolized corticosteroid is associated with increased side effects including hoarseness, sore throat, thrush, pneumonia, and osteoporosis; however, caution should be exercised in withdrawing inhaled glucocorticoid administration in patients with severe COPD receiving triple inhalation therapy. A stepwise approach to withdrawing inhaled corticosteroids may minimize the risk for acute exacerbations but a decrease in lung function can still occur after discontinuation.[30]

Inhaled anticholinergic drugs, including ipratropium and tiotropium, have an important role in the chronic management of patients with chronic bronchitis and COPD.[31] Inhaled long-acting muscarinic antagonists (LAMAs) alone or more frequently, when administered in combination with a LABA, improve lung function and symptom control and reduce the number of acute exacerbations. Triple combination inhalation therapy (eg, LABA + LAMA + an inhaled corticosteroid) is being evaluated in patients with more severe COPD with promising findings and its role remains to be defined.[32] Although once prescribed extensively for patients with chronic bronchitis, chronic theophylline therapy is used with decreasing frequency in favor of aerosolized β_2-receptor agonists, LABA, LAMA, etc. Nevertheless, long-acting theophylline remains an effective "add on" therapy for many patients, particularly those with more severe chronic bronchitis/COPD due to the drug's beneficial effects of bronchodilation, improved ciliary function and increased beat frequency, possibly increased mucus hydration, and low cost.[18]

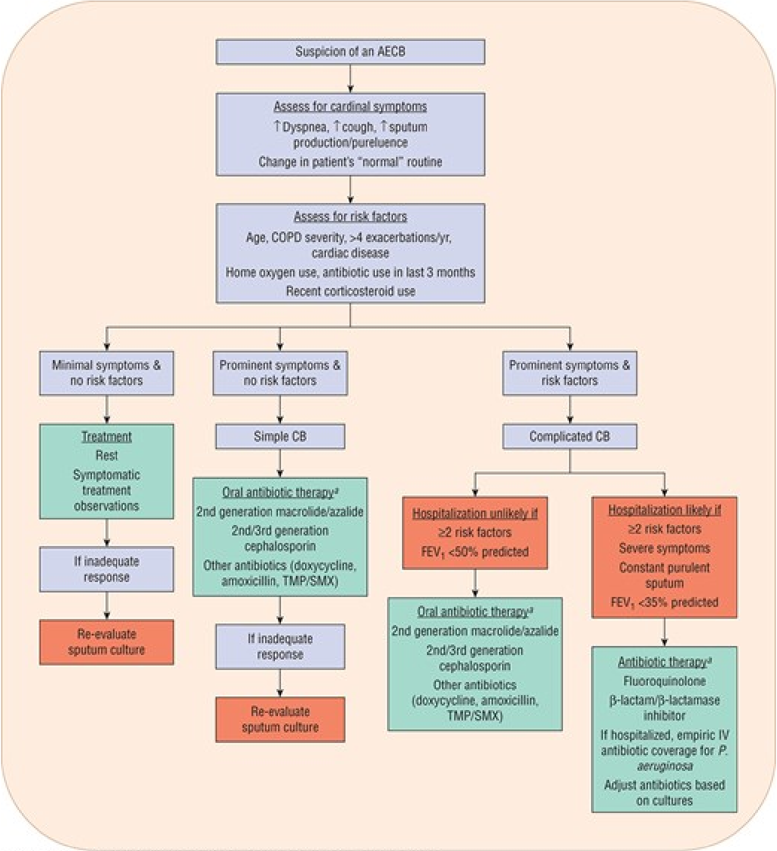
Phosphodiesterase 4 inhibitors (PDE-4), compared with the nonselective phosphodiesterase inhibitor theophylline, only affect phosphodiesterase in the airway smooth muscle, immune cells (eosinophils, monocytes, and neutrophils), and proinflammatory cells. Roflumilast is a highly specific (second generation) PDE-4 inhibitor that is most often reserved for use in patients with moderate to severe COPD. Considering that many of the published studies assessing the viability of second-generation PDE-4 inhibitors in patients with COPD involved patients with chronic cough and increased sputum production, it is inferred that these drugs would be of value in patients with chronic bronchitis as well. The GOLD guidelines suggest roflumilast reduces exacerbations in COPD patients with chronic bronchitis treated with oral glucocorticosteroids. Roflumilast only provides a net benefit to patients at high risk of severe exacerbations.[32,33] A lower 30-day readmission rate in patients hospitalized for COPD with roflumilast therapy was reported.[34] PDE-4 inhibitors improved lung function over placebo and reduced the likelihood of exacerbations; they had little impact on a patient's symptoms or quality of life. Nevertheless, the major limitation to the use of PDE-4 inhibitors is their side effect profiles. Patients receiving roflumilast often experience nausea, vomiting, headache, weight loss, insomnia, and an increased risk of psychiatric events.[35] The exact role of roflumilast in chronic lung disease is evolving but many guidelines suggest its use as add-on therapy for subgroups of patients.[32,35]

Use of antimicrobials for treatment of chronic bronchitis has been controversial, but is becoming more accepted in specific circumstances. Numerous comparative evaluations, including placebo-controlled studies of antibiotic administration for acute and chronic treatment of chronic bronchitis, have suggested clinical benefit. The antibiotics selected most frequently possess variable in vitro activity against the common sputum isolates *H. influenzae*, *S. pneumoniae*, *M. catarrhalis*, and *M. pneumoniae*. Conflicting published results appear independent of the antibiotic used or the regimen compared. A wide disparity that existed in the published results from older studies served as the basis for the enormous controversy about the use of antibiotics for the treatment of acute exacerbations of chronic bronchitis. Overall, good clinical results have been observed with the use of standard short-course antibiotic regimens (eg, macrolides, azalides, oral cephalosporins, and the combination drug amoxicillin-clavulanate, trimethoprim-sulfamethoxazole, and tetracyclines).[36,37] The goal is to select the most effective antibiotic drug for the patient based on their history of previous exacerbations and response to drug therapy. The introduction of genome expression profiling of sputum and other biologic fluids can facilitate specific pathogen diagnosis and focused therapy.[38]

A useful paradigm for the assessment and treatment of acute exacerbations of chronic bronchitis and antibiotic decision making is shown in Fig. 129-1.[39] Many clinicians use the so-called Anthonisen criteria to determine if antibiotic therapy is indicated.[24] With the Anthonisen criteria, if a patient exhibits two of the following three criteria during an acute exacerbation of chronic bronchitis (AECB), the patient will most likely benefit from antibiotic therapy and, thus, should receive a treatment course: (a) increase in shortness of breath; (b) increase in sputum volume; and (c) production of purulent sputum. There are greater healthcare costs for patients who are noncompliant with their antibiotic regimen for their AECB.

FIGURE 129-1

Clinical algorithm for the diagnosis and treatment of chronic bronchitis patients with an acute exacerbation incorporating the principles of the clinical classification system. (AECB, acute exacerbation of chronic bronchitis; CB, chronic bronchitis; COPD, chronic obstructive pulmonary disease; TMP/SMX, trimethoprim/sulfamethoxazole.)[a] See Table 129-3 for commonly used antibiotics and doses. *(Reprinted, with permission, from Hayes DJ, Meyer K. Acute exacerbations of chronic bronchitis in elderly patients: Pathogenesis, diagnosis, and management. Drugs Aging 2007;24:555–572.)*



Suspicion of an AECB
Assess for cardinal symptoms
↑Dyspnea, ↑cough, ↑sputum production/pureluence
Change in patient's "normal" routine
Assess for risk factors
Age, COPD severity, >4 exacerbations/yr, cardiac disease
Home oxygen use, antibiotic use in last 3 months
Recent corticosteroid use
Minimal symptoms & no risk factors
Prominent symptoms & no risk factors
Prominent symptoms & risk factors
Treatment
Rest
Symptomatic treatment observations
If inadequate response
Re-evaluate sputum culture
Simple CB
Oral antibiotic therapy^a
2nd generation macrolide/azalide
2nd/3rd generation cephalosporin
Other antibiotics (doxycycline, amoxicillin, TMP/SMX)
If inadequate response
Re-evaluate sputum culture
Complicated CB
Hospitalization unlikely if
≥2 risk factors
FEV₁ <50% predicted
Oral antibiotic therapy^a
2nd generation macrolide/azalide
2nd/3rd generation cephalosporin
Other antibiotics (doxycycline, amoxicillin, TMP/SMX)
Hospitalization likely if
≥2 risk factors
Severe symptoms
Constant purulent sputum
FEV₁ <35% predicted
Antibiotic therapy^a
Fluoroquinolone
β-lactam/β-lactamase inhibitor
If hospitalized, empiric IV antibiotic coverage for P. aeruginosa
Adjust antibiotics based on cultures

The increasing resistance of the common bacterial pathogens to first-line agents further complicates antibiotic selection. As many as 30% to 40% of *H. influenzae* isolates and 95% to 100% of *M. catarrhalis* isolates produce β-lactamases. Moreover, up to 40% of *S. pneumoniae* isolates demonstrate intermediate susceptibility (minimum inhibitory concentration [MIC] 0.125-1 mg/L) or resistance (MIC ≥ 2 mg/L) to oral penicillin, with approximately 20% of isolates being highly resistant (MIC > 2 mg/L). Concern regarding *S. pneumoniae* resistance is increasing, and resistance is now greater than or equal to 30% for macrolides. Despite these changes in bacterial susceptibility, the recommendation is to initiate therapy with first-line antimicrobial agents in less severely affected patients (see Fig. 129-1). For patients with more moderate to severe disease, many clinicians will begin antibiotic therapy with the second-line agents, such as amoxicillin-clavulanate, a macrolide (such as azithromycin or clarithromycin, although they are being used less frequently), or a fluoroquinolone, such as levofloxacin and moxifloxacin (see Fig. 129-1).

Regardless of the antibiotic selected, predetermined outcome measures should be monitored closely for each patient to determine the success or failure of the therapeutic intervention. Oral antibiotics with broader antibacterial spectra (eg, amoxicillin-clavulanate and fluoroquinolones) that possess potent in vitro activity against sputum isolates are increasingly becoming first-line antibiotics as initial therapy for treatment of acute exacerbations of chronic bronchitis.

An important clinical outcome variable directing drug selection and criteria for beginning antibiotics in individual patients is the infection-free period when they are off antibiotics. The length of the infection-free time period and the change in the number of physician office visits and hospital admissions with a particular antibiotic regimen are extremely important to identify, whenever possible, for each patient. The antibiotic regimen that results in the longest infection-free period defines the “regimen of choice” for specific patients for future acute exacerbations of their disease. Long-term prophylactic antibiotic use may provide a slight benefit in decreasing exacerbation rates, but does not appear to decrease mortality, and markedly increase the emergence and colonization of antibiotic-resistant pathogens. For this reason, most guidelines do not support this indication. However, chronic macrolide/azalide use reduces the incidence of acute exacerbations in COPD patients in a clinically significant manner (macrolide and anti-inflammatory activity addressed later).[39,40]

Antibiotics that are effective against responsible pathogens, demonstrate the least risk of drug interactions, and can be administered in a manner that promotes compliance should be selected. Antibiotics, commonly used for treatment of these patients with chronic bronchitis, and their respective adult starting doses are listed in Table 129-3. Doses of antibiotics should be adjusted as needed to the desired clinical effect and the lowest incidence of acceptable side effects. A frequently used clinical strategy to enhance the duration of symptom-free periods incorporates higher-dose antibiotic regimens using the upper limit of the recommended daily antibiotic dose. More clinicians are electing to limit their antibiotic treatment regimen to 5 days as compelling data continue to support equal efficacy, less exposure potentially reducing bacterial resistance development, and possibly less side effects with short-duration antibiotic therapy versus longer treatment regimens (greater than 7 days).

TABLE 129-3

Oral Antibiotics Commonly Used for the Treatment of Acute Respiratory Exacerbations in Chronic Bronchitis

Antibiotic	Brand Name	Usual Adult Oral Dose (mg)	Dose Schedule (Doses/Day)
Preferred Drugs			
Ampicillin	–	250-500	3-4
Amoxicillin	–	500-875	2-3
Amoxicillin-clavulanate	Augmentin®	500-875	2-3
Ciprofloxacin	Cipro®	500-750	2
Levofloxacin	Levaquin®	500-750	1
Moxifloxacin	Avelox®	400	1
Doxycycline	Monodox®	100	2
Minocycline	Minocin®	100	2
Tetracycline HCl	–	500	4
Trimethoprim-sulfamethoxazole	Bactrim DS®/Septra DS®	1 DS	2
Supplemental Drugs			
Azithromycin	Zithromax®	250-500	1
Erythromycin	Ery-Tab®/Erythrocin®	500	4
Clarithromycin	Biaxin®	250-500	2
Cephalexin	Keflex®	500	4

DS, double-strength tablet (160-mg trimethoprim/800-mg sulfamethoxazole).

Except for long-term macrolide/azalide administration, chronic antibiotic therapy is rarely indicated in the management of patients with chronic bronchitis. Such approaches lead to marked increase in cost and occurrence of multidrug-resistant (MDR) pathogens. Conversely, long-term macrolide (erythromycin, clarithromycin, and roxithromycin) or azalide (azithromycin) administration has been associated with a clinically significant reduction in the incidence of acute exacerbations in patients with chronic bronchitis and COPD.[39-41] The benefit of these drugs is attributed to their antibacterial, anti-inflammatory, and immunomodulatory activity. These drugs reduce bacterial adherence and toxin production, inhibit biofilm function, and reduce the generation of oxygen free radicals, modulate mucin gene protein production controlling mucus hypersecretion, and improve mucociliary clearance. These drugs also decrease neutrophil chemotaxis, promote downregulation of adhesion molecule expression, and inhibit transcription factors leading to decreased production of pro-inflammatory cytokines.[41]

The importance of multifactorial cellular oxidative stress in the pathogenesis of chronic bronchitis and COPD has prompted the study of the efficacy of antioxidants and particularly the oral administration of NAC, other mucolytic agents, and antioxidants.[27,42,43] Some guidelines suggest their use for more severely affected patients. Studies with oral NAC have suggested a dose-dependent response with 600 mg once to twice daily and it may slightly decrease the exacerbation rate in COPD patients not using inhaled steroids; however, there does not appear any effect on lung function. The exact role of antioxidant in the care of these patients remains to be defined—no specific recommendations can be provided until more data are available regarding which specific compound (as well as dose and duration of therapy) is optimal.

BRONCHIOLITIS

Epidemiology and Etiology

⑦ Bronchiolitis is an acute viral infection of the lower respiratory tract that affects approximately 50% of children during the first year of life and 100% by age 2 years. The occurrence of bronchiolitis peaks during the winter months and persists through early spring. Bronchiolitis remains the major reason for hospital admission during the first year of life.[44]

Respiratory syncytial virus (RSV) is the most common cause of bronchiolitis, accounting for up to 75% of all cases. During epidemic periods, the incidence of RSV-induced bronchiolitis may approach 90% of cases. Other frequently detectable viruses include human rhinovirus, coronavirus, parainfluenza, and adenovirus. Bacteria serve as secondary pathogens in a minority of cases.[44]

Clinical Presentation

The clinical presentation of bronchiolitis (Table 129-4) is often preceded by 1 to 4 days of symptoms (eg, nasal congestion, rhinorrhea, cough, and low-grade fever) indicative of an upper respiratory tract infection. Due to limited oral intake because of coughing combined with fever, vomiting, and diarrhea, infants frequently are dehydrated. The increased work of breathing and tachypnea most likely contribute to increased fluid loss. In most cases, bronchiolitis is self-limiting and typically symptoms improve within 7 to 10 days with resolution within 28 days without the need for hospitalization. In patients who require hospitalization, the average length of stay is approximately 3 days.[45]

TABLE 129-4

Clinical Presentation of Bronchiolitis

Signs and symptoms • Prodrome with irritability, restlessness, and mild fever • Cough and coryza • Vomiting, diarrhea, noisy breathing, and increased respiratory rate as symptoms progress • Labored breathing with retractions of the chest wall, nasal flaring, and grunting
Physical examination • Tachycardia and respiratory rate of 40-80 per minute in hospitalized infants • Wheezing and inspiratory rales • Mild conjunctivitis in one-third of patients • Otitis media in 5%-10% of patients
Laboratory tests • Peripheral white blood cell count normal or slightly elevated • Abnormal arterial blood gases (hypoxemia and, rarely, hypercarbia)

The diagnosis of bronchiolitis is based primarily on history and clinical findings. It is important for the clinician to attempt to differentiate between bronchiolitis and a host of other clinical entities affecting infants, which may produce a similar picture of dyspnea and wheezing. Asthma, congestive heart failure, anatomic airway abnormalities, cystic fibrosis, foreign bodies, and gastroesophageal reflux are the primary disease entities that may present with wheezing in children. Isolation of a viral pathogen in the respiratory secretions of a wheezing child establishes a presumptive diagnosis of infectious bronchiolitis. However, identification of specific viral pathogens often is hindered by the limited availability of special virology laboratories. In addition, in the elderly and in immunocompromised patients, antigen detection lacks adequate sensitivity, and patients frequently seek medical care after the acute stage of the infection, thus compromising the ability of the available tests to diagnose RSV. However, the proliferation of commercial enzyme-linked immunosorbent assays and fluorescent antibody staining techniques of nasopharyngeal secretions has increased the ability to identify viral antigens within several hours. Identification of RSV by PCR should be available from most clinical laboratories, but its relevance to the clinical management of bronchiolitis remains obscure and therefore routine testing is not recommended.[45,46]

Multiple clinical laboratory determinations have been used to assist in the management of cases of bronchiolitis. Radiographic evaluation of the chest in children with bronchiolitis yields variable findings and rarely alters therapeutic decisions. Thus, the routine use of chest radiography is not recommended; however, in hospitalized patients who fail to demonstrate expected improvement, they may help to distinguish bronchiolitis from other entities characterized by wheezing so that appropriate treatment may be initiated. In children requiring hospitalization, abnormalities in blood gas tensions are frequent and appear to relate to disease severity. Hypoxemia is common and increases the respiratory drive, whereas hypercarbia is seen in only the most severe cases. Despite the presence of moderate degrees of hypoxemia, clinical cyanosis is unusual.[44]

Treatment

Desired Outcome

In the well infant, bronchiolitis usually is a self-limiting illness, and reassurance, antipyretics, and adequate fluid intake usually are all that are necessary while waiting for resolution of the underlying viral infection. In-hospital support is necessary for the child suffering from respiratory failure or marked dehydration; underlying cardiac and pulmonary diseases potentiate these conditions.[45]

General Approach to Treatment

⑦ Almost all otherwise healthy babies with bronchiolitis can be followed as outpatients. Such infants are treated for fever, provided generous amounts of oral fluids, and observed closely for evidence of respiratory deterioration.[44] In severely affected children, the mainstays of therapy for bronchiolitis are oxygen therapy and IV fluids. In a subset of patients, aerosolized bronchodilators may have a role. For selected infants, particularly those with underlying pulmonary disease, cardiac disease, or both, therapy with the antiviral agent ribavirin can be considered.[47]

Pharmacologic Therapy

⑦ Aerosolized β_2-adrenergic therapy appears to offer little benefit for most patients and may even be detrimental.[46-48] Given their overall ineffectiveness, neither aerosolized β_2-adrenergic nor nebulized epinephrine therapies are recommended by the American Academy of Pediatrics (AAP) for the treatment of bronchiolitis.[48,49] Multiple studies have supported the AAP recommendations due to insufficient evidence for the effectiveness of bronchodilators in bronchiolitis, although there may be subgroups of patients who might benefit.[48-50]

Similarly, controlled trials of corticosteroids in bronchiolitic infants have not shown therapeutic effects or significant harmful effects, though viral shedding may be prolonged.[45,48] As a result, the routine use of systemically administered corticosteroids is not recommended by the AAP and is therefore discouraged.[46,48] Combination therapy with oral dexamethasone and nebulized epinephrine may act synergistically to reduce hospital admissions and shorten the time to discharge and the duration of symptoms, but the overall clinical benefits is questionable based on study results.[49] Although placing children with bronchiolitis in mist tents has been common practice, no data have documented the effectiveness of this practice.

The AAP guidelines support the use of nebulized hypertonic saline (eg, 3% saline) for the treatment of bronchiolitis in hospitalized infants and children while other international guidelines do not recommend its use.[46,48] As such, although nebulized hypertonic saline has proven to be safe and effective for the symptomatic improvement in patients with bronchiolitis after 1 day of use, there continues to be debate on if it reduces the length of hospital stay.[51]

Ribavirin may offer benefit to a subset of infants with bronchiolitis. Ribavirin, a synthetic nucleoside, possesses in vitro antiviral properties against a variety of RNA and DNA viruses, including influenza A, influenza B, parainfluenza, and adenovirus; it is approved only in aerosolized form against RSV. Use of the aerosol drug formulation requires special equipment (small-particle aerosol generator) and specially trained personnel for administration via oxygen hood or mist tent. Special care must be taken to avoid drug particle deposition and the resulting clogging of respiratory tubing and valves in mechanical ventilators. Among hospital admissions for RSV infection, ribavirin therapy failed to decrease length of hospital stay, number of days in the intensive care unit, or number of days receiving mechanical ventilation. Consequently, the AAP does not recommend the routine use of ribavirin in children with bronchiolitis and most experts recommend reserving use of ribavirin for severely ill patients.[48]

For infants with underlying pulmonary or cardiovascular disease, prophylaxis against RSV may be warranted. When administered monthly during the RSV season, both RSV immune globulin and palivizumab (a monoclonal antibody for RSV) may decrease the number of RSV episodes and the need for hospitalization. Between the two, palivizumab is preferred, given its ease of administration, lack of administration-related adverse effects, and noninterference with select immunizations. Despite continuing research, there is no vaccine marketed for RSV.

PNEUMONIA

Epidemiology

Pneumonia remains one of the most common causes of severe sepsis and the leading infectious cause of death in children and adults in the United States, with a mortality rate as high as 50% depending on the severity of illness.[5,52] Pneumonia occurs throughout the year, with the relative incidence of disease resulting from different etiologic entities varying with the seasons. It occurs in persons of all ages, although the clinical manifestations are most severe in the very young, the elderly, and the chronically ill.

Pathogenesis and Etiology

Inspiration of ambient air constantly exposes the lungs to environmental and infectious particulate matter. Respiratory pathogens enter the lower respiratory tract by one of three routes: (1) direct inhalation of infectious droplets; (2) aspiration of oropharyngeal contents; or (3) hematogenous spread from another infection site. Respiratory host defenses comprise innate and adaptive immunity pathways. These defense mechanisms are preserved in healthy individuals and respiratory pathogens are effectively removed before infection occurs. Conversely, immunocompromised individuals (such as those with cystic fibrosis or prolonged neutropenia) lack robust defense mechanisms and are at higher risk of severe respiratory infections. Lung infections can also suppress the antibacterial activity of the lung by impairing alveolar macrophage function and mucociliary clearance, thus setting the stage for secondary bacterial pneumonia. Mucociliary transport is also depressed by ethanol and narcotics and by obstruction of bronchi by mucus, tumor, or extrinsic compression. All these factors can severely impair pulmonary clearance of aspirated bacteria. Any alteration of the normal lung microbiome by infection and/or disease can evolve to pneumonia requiring antimicrobial treatment.[53]

Pneumonia is caused by a variety of viral and bacterial pathogens. The causative organism(s) is highly dependent on how and/or where the pneumonia was contacted.[4-6,54] For epidemiologic and treatment purposes, pneumonia is often categorized as either community-acquired or hospital-acquired (Table 129-5).[6] Patients with pneumonia onset outside of the hospital or within 48 hours of hospital admission are considered to have community-acquired pneumonia (CAP). Those with pneumonia onset in the hospital after at least 48 hours of hospitalization are considered to have hospital-acquired pneumonia (HAP). Patients with pneumonia onset following 48 hours of endotracheal intubation are considered to have ventilator-associated pneumonia (VAP).

TABLE 129-5

Pneumonia Classifications and Risk Factors

Type of Pneumonia	Definition	Risk Factors
Community-acquired pneumonia	Pneumonia developing outside the hospital or <48 hours after hospital admission	• Age >65 years • Diabetes mellitus • Asplenia • Chronic cardiovascular, pulmonary, renal, and/or liver disease • Smoking and/or alcohol abuse
Hospital-acquired pneumonia	Pneumonia developing >48 hours after hospital admission	• Witnessed aspiration • COPD, ARDS, or coma • Administration of antacids, H_2-antagonists, or proton pump inhibitor • Supine position • Enteral nutrition, nasogastric tube • Reintubation, tracheostomy, or patient transport • Head trauma, ICP monitoring • Age >60 years • MDR risk (eg, MRSA, MDR *Pseudomonas*) if IV antibiotic use within 90 days
Ventilator-associated pneumonia	Pneumonia developing >48 hours after endotracheal intubation	• Same as hospital acquired • MDR risk with IV antibiotics in past 90 days, septic shock, ARDS preceding VAP, acute renal replacement therapy preceding VAP, or 5+ days of hospitalization preceding VAP

ARDS, acute respiratory distress syndrome; CAP, community-acquired pneumonia; COPD, chronic obstructive pulmonary disease; HAP, hospital-acquired pneumonia; ICP, intracranial pressure; MDR, multidrug-resistant; MRSA, methicillin-resistant *S. aureus*; VAP, ventilator-associated pneumonia.

Community-Acquired Pneumonia

8 The causative pathogen in CAP in adult patients is most commonly viral, with human rhinovirus and influenza most common.[55] The most prominent bacterial pathogen causing CAP in otherwise healthy adults is *S. pneumoniae* accounting for up to 35% of all acute cases. It is particularly prevalent and severe for patients with splenic dysfunction, diabetes mellitus, chronic cardiopulmonary or renal disease, or HIV infection. Other common pathogens include *H. influenzae* (2.5%-45%) and the atypical pathogens *M. pneumoniae*, *Legionella* species, and *C. pneumoniae* (about 20%).[55-57] Although generally less common, *S. aureus* is also an important CAP pathogen in children and adults and is often seen in patients with cystic fibrosis and those recovering from an antecedent viral respiratory infection such as influenza. CAP caused by enteric gram-negative bacteria, including *E. coli* and *K. pneumoniae*, is also uncommon but these pathogens are sometimes identified; most frequently among patients with chronic illness, especially alcoholism and diabetes mellitus.[4] Healthcare-associated pneumonia was a classification that had been previously used to distinguish nonhospitalized patients at risk for MDR pathogens from those likely infected with traditional CAP pathogens; however, it is no longer recommended to risk stratify patients using this designation.[4,6]

Even more so than in adult patients, viral pathogens predominate in CAP among pediatric patients with a prevalence of up to 80% in those less than 2 years of age. Respiratory syncytial virus and human rhinovirus comprise the majority of these infections.[58] Other common viruses in children include parainfluenza, adenovirus, human metapneumovirus, and bocavirus.[5,58] Group B *Streptococcus*, although rare in adults, is the most common cause of bacterial pneumonia among neonates and typically causes a clinical and radiographic picture nearly indistinguishable from hyaline membrane disease.[59] The bacterial causes of CAP outside the neonatal period are generally similar to adults, with *S. pneumoniae* being the major bacterial pathogen in childhood pneumonia.[58] *M. pneumoniae* is also common, particularly among older children. *H. influenzae* type b, once a major childhood pathogen, has become an infrequent cause of pneumonia since the introduction of active vaccination against this organism in the late 1980s.

Hospital-Acquired Pneumonia

8 HAP occurs most commonly in critically ill patients and is usually caused by bacteria.[6] Factors predisposing patients to the development of HAP include high severity of illness, longer duration of hospitalization, supine positioning, witnessed aspiration, coma, acute respiratory distress syndrome, patient transport, and prior antibiotic exposure (Table 129-5). The strongest predisposing factor, however, is mechanical ventilation (intubation). The length of stay for hospital admissions is increased by a mean of 7 to 9 days for patients who develop HAP.[6]

HAP is predominantly caused by gram-negative aerobic bacilli or *S. aureus* and is much more likely to be caused by an MDR isolate.[6] Collectively, the non-lactose fermenting gram-negative bacilli *P. aeruginosa* and *Acinetobacter* spp. are the most common cause of HAP (about 25%-45%).[6] Enteric gram-negative bacilli such as *K. pneumoniae* and *E. coli* are also common (13%-20%).[6] *S. aureus* is also common (12%-21%) with approximately half of these isolates methicillin-resistant.[6] Patients with longer lengths of hospital admission or IV antibiotic use within the previous 90 days preceding HAP development are more likely to have MDR organisms.[6]

HAP can be subclassified as ventilator-associated pneumonia (VAP), which is pneumonia occurring after 48 or more hours of endotracheal intubation.[6] The risk for developing pneumonia in the hospital increases by 6 to 21 times after a patient is intubated because the natural airway defenses against the migration of upper respiratory tract organisms into the lower tract are bypassed.[6] This situation is exacerbated by the wide use of acid-suppressing drugs (eg, H_2-receptor blocking agents and proton pump inhibitors) in the intensive care unit, which increases the pH of gastric secretions and may promote the proliferation of microorganisms in the upper GI tract. Subclinical microaspirations are events that occur routinely in intubated patients and result in the inoculation of bacteria-contaminated gastric contents into the lung and a higher incidence of nosocomial pneumonia.[60] Although generally similar in etiology to HAP, VAP is more likely to be caused by *S. aureus* (20%-30%) and multidrug resistance is more common.[6,61,62]

Aspiration pneumonia is classically treated as a separate entity from CAP or HAP. It was predominantly caused by anaerobic bacteria that commonly colonize the oropharynx. The epidemiologic evidence suggests a decreasing importance of anaerobic bacteria in aspiration pneumonia. Aspiration pneumonia has a bacteriology similar to CAP or HAP, and anaerobic pathogens are less common and typically seen in patients with specific risk factors such as severe periodontal disease or those with specific clinical findings such as necrotizing pneumonia or lung abscess.[54]

Tuberculosis

The acid-fast bacillus *Mycobacterium tuberculosis* causes tuberculosis and is spread person to person by inhalation of droplets. After years of steady decline, the number of cases of pneumonia caused by *M. tuberculosis* in the United States began to increase in the mid- to late 1980s. The new epidemic was a consequence of an increased incidence among prison inmates, IV drug abusers, immigrants, and, most prominently, HIV-infected patients. It is most prominent in urban neighborhoods afflicted with crowded living conditions and poor access to health care; thus, groups prone to tuberculosis include the homeless and patients in chronic care facilities and homes for the elderly. Unlike previous eras in which tuberculosis was seen most frequently in elderly men, infection currently is identified in increasing numbers of young adults. MDR strains of *M. tuberculosis* have become more common, and treatment regimens for these patients should involve consultation with a specialist. (See Chapter 135, “Tuberculosis” for a detailed discussion of tuberculosis pathophysiology, diagnosis, and treatment.)

Clinical Presentation and Diagnosis

The common signs, symptoms, physical exam findings, and diagnostic features of patients with pneumonia are listed in Table 129-6. They are both constitutional (fever, chills, malaise) and respiratory (cough, increased sputum production, dyspnea). These signs and symptoms coupled with physical exam findings suggestive of a pulmonary infiltrate, with or without abnormal whiteblood cell (WBC) count or oxygen saturation, can form the basis of a presumed clinical diagnosis of pneumonia. The diagnosis of pneumonia is preferably further strengthened by radiographic evidence such as pulmonary infiltrate(s) on chest x-ray or another chest imaging. Clinical practice guidelines recommend a chest radiograph for all adult patients with suspected pneumonia but only in select pediatric patients with severe CAP (eg, inpatient, signs of hypoxia/respiratory distress).[4-6]

TABLE 129-6

Clinical Presentation of Pneumonia

Signs and symptoms

- Abrupt onset of fever, chills, dyspnea, and productive cough
- Rust-colored sputum or hemoptysis
- Pleuritic chest pain
- Dyspnea

Physical examination

- Tachypnea and tachycardia
- Dullness to percussion
- Increased tactile fremitus, whisper pectoriloquy, and egophony
- Chest wall retractions and grunting respirations
- Diminished breath sounds over affected area
- Inspiratory crackles during lung expansion

Chest radiograph

- Dense lobar or segmental infiltrate

Laboratory tests

- Leukocytosis with predominance of polymorphonuclear cells
- Low oxygen saturation on arterial blood gas or pulse oximetry

Clinical and radiographic data can begin to shape the differential diagnosis of suspected pneumonia pathogens. Pneumonia caused by the atypical pathogens, such as *M. pneumoniae* and *C. pneumoniae,* often has a more gradual onset and overall lower severity compared with other bacterial causes.[64,65] The exception to this is *Legionella pneumophila*, which is an atypical pathogen that often causes severe illness making it a common pathogen in patients with CAP who require ICU admission.[64,118] Patients with atypical pneumonia also commonly have extrapulmonary, constitutional symptoms.[64,65] Atypical pneumonias often demonstrate patchy infiltrates on chest x-ray that are more extensive than clinical symptoms suggest, hence the term "walking pneumonia."[66] Chest radiographs in patients with viral etiology are often diffuse, interstitial compared with the classic lobar or lobular consolidated infiltrates of bacterial pneumonia. Staphylococcal pneumonias often demonstrate cavitary or necrotizing lesions on imaging. Although these general clinical and diagnostic characteristics can be useful, there is considerable overlap in clinical presentation between pneumonia etiologies. These data alone are not sufficiently reliable to differentiate between bacterial, atypical bacterial, and viral etiology.[67] Similarly, the use of biomarkers, such as procalcitonin, is not recommended to differentiate between bacterial and viral pneumonia.[4,6]

⑩ Following a pneumonia diagnosis based on clinical and radiographic evidence, further diagnostic testing to confirm the diagnosis and determine the etiology may be warranted. Blood cultures and noninvasive sputum cultures (ie expectorated sputum, sputum induction, or nasotracheal suctioning) are recommended for all adult patients with suspected HAP or VAP.[6] Blood cultures often provide value in determining the causative pathogen, particularly in VAP where approximately 15% of patients have concomitant bacteremia.[68,69] Emphasis is placed on determining an etiology in HAP and VAP due to the high prevalence of MDR organisms and associated risk of ineffective empiric therapy. This allows adjustment of initial empiric therapy into optimal, pathogen-specific therapy.

Confirmation of etiology is less common in CAP, where a microbiologically confirmed etiology is identified in only 7% of cases in clinical practice.[70] As such, empiric treatment of CAP is often continued for the entire duration of therapy without ever determining the causative pathogen. Cultures are only routinely recommended in patients with more severe CAP where knowledge of the causative pathogen and whether the empiric antibiotic regimen is active are most important. In patients treated in the outpatient setting, sputum cultures are not routinely recommended. The exceptions to this are pediatric patients who have experienced failure of initial antibiotics and adult patients treated with empiric antibiotics that cover MRSA and/or *P. aeruginosa*.[4,5] Blood and sputum cultures are recommended in hospitalized adult patients with severe CAP. This includes, but is not limited to, patients with septic shock requiring vasopressors and/or those with respiratory failure requiring mechanical ventilation (Table 129-7). Blood and sputum cultures are also recommended in hospitalized adult patients receiving empiric therapy covering MRSA and/or *P. aeruginosa* or among considered at risk for these pathogens.[4] Sputum Gram stain and culture are recommended for hospitalized children who can produce a sputum sample along with blood cultures in those with moderate/severe CAP.[5] Urinary antigen tests are also available for *S. pneumoniae* and *L. pneumophila*, and are recommended in adults with severe CAP.[4] These tests are more rapid than traditional microbiologic methods and can detect pathogen antigen days (*S. pneumoniae*) to weeks (*L. pneumophila*) after initiation of antibiotic therapy.[71] These tests have a high specificity (90%-99%) but lower sensitivity (50%-80%). This translates to few false-positives and more false-negatives, making it a useful test to “rule in” these pathogens in adult patients.[63,72,73] Rapid diagnostic tests for viruses, including influenza, are also recommended in children with suspected CAP. Influenza nucleic acid amplification testing is also recommended in adult patients when influenza is circulating in the community. A positive result in combination with an absence of clinical factors strongly suggestive of bacterial infection can be used to reduce unnecessary antibiotic use.[5] It would also be prudent to perform nucleic acid amplification testing for SARS-CoV-2 when it is circulating in the community.

TABLE 129-7

Severe CAP Criteria

Major Criteria – 1 or more defines severe CAP Septic shock with need for vasopressors Respiratory failure requiring mechanical ventilation
Minor Criteria – 3 or more defines severe CAP Respiratory rate > 30 breaths/min PaO_2/FIO_2 ratio < 250 Multilobar infiltrates Confusion/disorientation Uremia (blood urea nitrogen level > 20 mg/dL [7.1 mmol/L]) Leukopenia (white blood cell count < 4,000 cells/mm^3 [4 x 10^9/L]) Thrombocytopenia (platelet count < 100,000/mm^3 [100 x 10^9/L]) Hypothermia (core temperature < 36°C) Hypotension requiring aggressive fluid resuscitation

Treatment Goals

Eradication of the offending organism through selection of the appropriate antibiotic(s) and subsequent complete clinical cure is the primary goal of therapy of pneumonia. Secondary goals include minimization of the unintended consequences of therapy, including toxicities and selection for secondary infections such a *Clostridioides difficile* or antibiotic-resistant pathogens, and minimizing costs through outpatient and oral therapy when the patient’s severity of illness and clinical considerations permit.

General Approach to Treatment

⑨ Achievement of the goals of therapy for pneumonia treatment requires the provider to follow the principles of good antimicrobial stewardship while ensuring adequate treatment of the potential infection. Comprehensive principles of optimal antimicrobial therapy and infectious diseases stewardship are discussed in detail in Chapter 127, “Antimicrobial Regimen Selection.” In general, antimicrobial stewardship involves provision of the right antimicrobial(s) (or lack thereof when infection is not present); at the right time, at the right dose, for the right duration. This is often a balance between providing therapy broad enough to cover likely pathogens but not overly broad resulting in potentially unnecessary drug toxicity, secondary infection, or antibiotic resistance. This also involves continual monitoring of patient clinical status and diagnostic data to support the decision to either continue empiric therapy, narrow or alter therapy, or discontinue therapy if infection is ruled out. This section discusses the selection of antimicrobial regimens in patients with a suspected or confirmed diagnosis of pneumonia.

Following diagnosis of the pneumonia, one of the first treatment decisions is what level of medical care is necessary (ie, outpatient vs inpatient vs inpatient ICU). This decision is ultimately made by a physician and should be based on the patient's severity of illness and subsequent risk of mortality. However, it is important for pharmacists to be able to perform and understand this severity assessment because it should be used to recommend the appropriate diagnostic monitoring and empiric antimicrobial therapy. Multiple severity scores designed to estimate mortality risk in CAP are available for severity assessment.[74,75] The preferred severity score for determining whether hospital admission is appropriate is the Pneumonia Severity Index (PSI), also known as Pneumonia Outcomes Research Team (PORT) score.[4,76] The PSI score utilizes age, comorbidities, physical exam findings, diagnostic test results, and laboratory test results to compute a patient's mortality risk. The PSI score identifies patients with low mortality risk allowing them to be safely treated in the outpatient setting.[4] The extensive laboratory and physiologic data required to calculate the PSI score is often not readily available upon patient presentation or in the outpatient setting.[76] The CURB-65 or CRB-65 scores may be used in these cases.[74,75] These short, simple point systems can easily be applied at the point of care using readily available clinical data. For CURB-65, patients receive 1 point for each criterion present: **C**onfusion, **U**remia (BUN > 20 mg/dL [7.1 mmol/L]), **R**espiratory rate ≥30 breaths/min, **B**lood pressure (systolic <90 mm Hg, diastolic ≤60 mm Hg), age ≥65 years. CRB-65 is a simplified version of CURB-65 that does not require knowledge of serum BUN concentration. Patients with CURB-65 or CRB-65 scores <2 are generally candidates for outpatient treatment.[4] Patients with a score of 2 or more are typically admitted to the general ward or ICU.[4] The severe CAP criteria listed in Table 129-7 are recommended to determine whether ICU care is necessary. Patients with one major criteria should be admitted to ICU. Minor criteria should be used in conjunction with clinical judgment when neither of the major criteria is present. Although guidelines do not state a specific number of minor criteria necessitating ICU admission, data indicate patients with three or more minor criteria are often admitted to the ICU in practice.[4]

Empiric Antimicrobial Treatment

Treatment of bacterial pneumonia, like the treatment of most infectious diseases, initially involves the empirical use of a relatively broad-spectrum antibiotic therapy that is effective against probable pathogens after appropriate cultures and specimens for laboratory evaluation have been obtained as indicated.[56,77] Therapy should be narrowed to cover specific pathogens after the results of cultures are known in cases where cultures are obtained. Multiple factors can aid in identifying the potential pathogens involved, including when and where the pneumonia was contracted, local pathogen epidemiology and susceptibility patterns, and individual patient factors. These individual patient factors include patient age, previous and current medication history, underlying disease(s), major organ function, and present clinical status. These factors must be evaluated to select an appropriate and effective empirical antibiotic regimen as well as the most appropriate route for drug administration (oral vs parenteral). (For a more detailed discussion on the principles of antibiotic selection, see Chapter 127.)

Because many antibiotics are effective in the treatment of bacterial pneumonia, and superiority of one antibiotic over another is often unclear or difficult to define, there are a variety of recommended empiric antimicrobial regimens for suspected bacterial pneumonia. For a list of potential empiric antimicrobial regimens, based on available clinical practice guidelines, primary literature, and antimicrobial susceptibility and PK/PD, refer to Table 129-8 for adults and Table 129-9 for children. A complete list of antimicrobial agents for specific pathogens is beyond the scope of this chapter and is presented in Chapter 127. Table 129-10 lists dosages for selected antibiotics used for the treatment of bacterial pneumonia.

TABLE 129-8

Evidence-Based Empirical Antimicrobial Therapy for Pneumonia in Adults[a]

Clinical Setting and/or Patient Characteristics	Usual Pathogens	Empirical Therapy
Outpatient/Community-Acquired		

No at-risk comorbidity (diabetes, heart/lung/liver/renal disease, alcoholism, malignancy, asplenia)	*S. pneumoniae*, *M. pneumoniae*, *H. influenzae*, *C. pneumoniae*, *M. catarrhalis*	Amoxicillin (preferred) OR Doxycycline (2nd preferred) OR Macrolide[b] (non-preferred)
At-risk comorbidity (diabetes, heart/lung/liver/renal disease, alcoholism, malignancy, asplenia) OR immunosuppressive condition/drugs	*S. pneumoniae (including drug-resistant)*, *M. pneumoniae*, *H. influenzae*, *C. pneumoniae*, *M. catarrhalis*	Antipneumococcal fluoroquinolone[c] OR β-lactam[d] + EITHER macrolide[b] OR doxycycline
Inpatient/Community-Acquired		
Non-severe CAP	*S. pneumoniae*, *H. influenzae*, *M. pneumoniae*, *C. pneumoniae*, *Legionella* sp. If prior respiratory MRSA (1 year) If prior respiratory *P. aeruginosa* (1 year) If prior hospitalization AND IV antibiotic (90 days) OR locally validated risk factor	*β*-lactam[e] + EITHER macrolide[b] OR doxycycline OR Antipneumococcal fluoroquinolone[c] ADD vancomycin OR linezolid AND obtain cultures, de-escalate in 48 hr if MRSA negative and clinically improving ADD[f] cefepime, piperacillin-tazobactam, ceftazidime, imipenem, meropenem, OR aztreonam AND obtain cultures, de-escalate in 48 hr if *P. aeruginosa* negative and clinically improving Obtain cultures, escalate if needed based on results
Severe CAP	*S. pneumoniae*, *H. influenzae*, *M. pneumoniae*, *C. pneumoniae*, *Legionella* sp. If prior respiratory MRSA (1 year) If prior respiratory *P. aeruginosa* (1 year) If prior hospitalization AND IV antibiotic (90 days)	*β*-lactam[e] + EITHER macrolide[b] OR antipneumococcal fluoroquinolone[c] ADD vancomycin OR linezolid AND obtain cultures, de-escalate in 48 hr if MRSA negative and clinically improving ADD[f] cefepime, piperacillin-tazobactam, ceftazidime, imipenem, meropenem, OR aztreonam AND obtain cultures, de-escalate in 48 hr if *P. aeruginosa* negative and clinically improving ADD vancomycin OR Linezolid AND ADD[e] cefepime, ceftazidime, imipenem, meropenem, piperacillin-tazobactam, OR aztreonam AND obtain cultures, de-escalate if MRSA/*P. aeruginosa*-negative and clinically improving
Hospital-Acquired Pneumonia		
Low mortality risk[g] AND No MDR HAP[h] risk factors AND Local MRSA prevalence <20%	Non-fermenting gram-negative bacilli[i], enteric gram-negative bacilli, MSSA	Piperacillin-tazobactam, cefepime, levofloxacin, imipenem, OR meropenem
Low mortality[g] risk AND No MDR HAP[h] risk factors AND Local MRSA ≥20% OR unknown High mortality risk[g] OR MDR risk factor(s)[h]	Non-fermenting gram-negative bacilli[i], enteric gram-negative bacilli, MRSA Non-fermenting gram-negative bacilli[i], enteric gram-negative bacilli, MRSA	Piperacillin-tazobactam, cefepime, levofloxacin, ciprofloxacin, imipenem, meropenem, OR aztreonam + vancomycin OR linezolid Double cover *P. aeruginosa* with two of the following, avoiding two from the same class: piperacillin-tazobactam, cefepime, levofloxacin, ciprofloxacin, imipenem, meropenem, aztreonam, gentamicin, tobramycin, amikacin + vancomycin OR linezolid

Ventilator-Associated Pneumonia		
No MDR VAP risk factors[i] AND Local MRSA and gram-negative bacilli-resistance both <10%[j] No MDR VAP risk factors[i] AND Local MRSA ≥10% or unknown AND gram-negative bacilli-resistance <10%[j] MDR VAP risk factor(s)[i] OR local MRSA and gram-negative bacilli-resistance >10%[j] or unknown	Non-fermenting gram-negative bacilli, enteric gram-negative bacilli, MSSA Non-fermenting gram-negative bacilli, enteric gram-negative bacilli, MRSA MDR non-fermenting gram-negative bacilli, MDR enteric gram-negative bacilli, MRSA	Piperacillin-tazobactam, cefepime, levofloxacin, imipenem OR meropenem Piperacillin-tazobactam, cefepime, levofloxacin, ciprofloxacin, imipenem, meropenem, OR aztreonam + vancomycin OR linezolid Double cover *P. aeruginosa* with two of the following, avoiding two from the same class: piperacillin-tazobactam, cefepime, levofloxacin, ciprofloxacin, imipenem, meropenem, aztreonam, gentamicin, tobramycin, amikacin, colistin, polymyxin B + vancomycin OR linezolid
Aspiration Pneumonia		
Community-acquired Hospital-acquired	*S. pneumoniae*, *M. pneumoniae*, *H. influenzae*, *C. pneumoniae* *S. aureus*, *P. aeruginosa* enteric gram-negative bacilli *If anaerobes suspected*	Treat as above for CAP Treat as above for HAP Treat as above for CAP/HAP using antibiotic with anaerobic coverage OR add clindamycin OR metronidazole

[a] See the section Selection of Antimicrobial Agents.

[b] Macrolide: erythromycin, clarithromycin, and azithromycin.

[c] Antipneumococcal fluoroquinolone: levofloxacin and moxifloxacin.

[d] Infectious Diseases Society of America recommended outpatient β-lactams: high-dose amoxicillin or amoxicillin/clavulanate preferred, cefpodoxime, cefuroxime, ceftriaxone (intramuscular) alternatives.

[e] Infectious Diseases Society of America recommended inpatient β-lactams: ceftriaxone (intravenous), cefotaxime, ampicillin, ampicillin-sulbactam, ceftaroline.

[f] If β-lactam-based CAP regimen selected, substitute antipseudomonal β-lactam for standard CAP β-lactam, unless ceftazidime or aztreonam chosen.

[g] Indicators of high HAP mortality risk: need for ventilator support due to pneumonia; septic shock.

[h] MDR HAP risk factors: receipt of IV antibiotics in previous 90 days; structural lung disease (bronchiectasis or cystic fibrosis).

[i] MDR VAP risk factors: receipt of IV antibiotics in previous 90 days; septic shock; acute respiratory distress syndrome preceding VAP; ≥5 days hospitalization preceding VAP; acute renal replacement therapy preceding VAP.

[j] Resistance to antibiotic being considered for empiric gram-negative monotherapy. MDR, multidrug resistant; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-sensitive *Staphylococcus aureus*.

TABLE 129-9

Empirical Antimicrobial Therapy for Pneumonia in Pediatric Patients[a]

Clinical Setting and/or Patient Characteristics	Usual Pathogen(s)	Empirical Therapy
Outpatient/Community-Acquired		
<1 month	Group B *Streptococcus*, *H. influenzae* (nontypable), *E. coli*, *S. aureus*, *Listeria* CMV, RSV, adenovirus	Ampicillin-sulbactam, cephalosporin,[b] carbapenem[c] Ribavirin for RSV[d]
1-3 months	*C. pneumoniae*, possibly *Ureaplasma*, CMV, *Pneumocystis carinii* (afebrile pneumonia syndrome) *S. pneumoniae*, *S. aureus*	Macrolide/azalide,[e] trimethoprim–sulfamethoxazole Semisynthetic penicillin[f] OR cephalosporin[g]
Preschool-aged children	Viral (rhinovirus, RSV, influenza A and B, parainfluenzae, adenovirus, human metapneumovirus, coronavirus)	Antimicrobial therapy not routinely required
Previously healthy, fully immunized infants and preschool children with suspected mild-to-moderate bacterial CAP	*S. pneumonia* *M. pneumoniae*, other atypical	Amoxicillin, cephalosporin[b,g] Macrolide/azalide or fluoroquinolone
Previously healthy, fully immunized school-aged children and adolescents with mild-to-moderate CAP	*S. pneumonia* *M. pneumoniae*, other atypical	Amoxicillin, cephalosporin,[b,g] or fluoroquinolone Macrolide/azalide, fluoroquinolone, or tetracycline
Moderate-to-severe CAP during influenza virus outbreak	Influenza A and B, other viruses	Oseltamivir or zanamivir
Inpatient/Community-Acquired		
Fully immunized infants and school-aged children	*S. pneumonia* CA-MRSA *M. pneumoniae*, *C. pneumoniae*	Ampicillin, penicillin G, cephalosporin[b] β-Lactam + vancomycin/clindamycin β-Lactam + macrolide/fluoroquinolone/doxycycline
Not fully immunized infants and children; regions with invasive penicillin-resistant pneumococcal strains; patients with life-threatening infections	*S. pneumoniae*, PCN-resistant MRSA *M. pneumoniae*, other atypical pathogens	Cephalosporin[b] Add vancomycin/clindamycin Macrolide/azalide[e] + β-lactam/doxycycline/fluoroquinolone

[a] See the section Selection of Antimicrobial Agents.

[b] Third-generation cephalosporin: ceftriaxone and cefotaxime. Note that cephalosporins are not active against *Listeria*.

[c] Carbapenem: imipenem–cilastatin and meropenem.

[d] See text for details regarding possible ribavirin treatment for RSV infection.

[e] Macrolide/azalide: erythromycin and clarithromycin/azithromycin.

[f] Semisynthetic penicillin: nafcillin and oxacillin.

[g] Second-generation cephalosporin: cefuroxime and cefprozil.

CAP, community-acquired pneumonia; CMV, cytomegalovirus; MRSA, methicillin resistant *Staphylococcus aureus*; RSV, respiratory syncytial virus.

Data from Reference 5.

TABLE 129-10

Antibiotic Doses for Treatment of Bacterial Pneumonia

Antibiotic Class	Antibiotic	Antibiotic Dose[a]	
		Pediatric	Usual Adult Dose
Penicillin	Ampicillin ± sulbactam Amoxicillin ± clavulanate[b] Piperacillin-tazobactam Penicillin	150-200 mg/kg/day IV 45-100 mg/kg/day orally 200-300 mg/kg/day IV 100,000-250,000 units/kg/day IV	2 g IV every 4-6 h (6 hr if ampicillin/sulbactam) 875-2,000 mg orally twice daily 3.375-4.5 g IV every 6-8 hr 12-24 million units/day in divided doses IV every 4-6 hr
Extended-spectrum cephalosporins	Ceftriaxone Cefotaxime Ceftazidime Cefepime Ceftolozane-tazobactam Ceftazidime-avibactam Cefiderocol	50-75 mg/kg/day IV 150 mg/kg/day IV 90-150 mg/kg/day IV 100-150 mg/kg/day IV – –	1-2 g IV daily 1-2 g IV every 8 hr 1-2 g IV every 8 hr 1-2 g IV every 6-8 hr 3 g IV every 8 hr 2.5 g IV every 8 hr 2 g IV every 8 hr
Monobactam	Aztreonam	90-120 mg/kg/day IV	1-2 g IV every 8 hr
Macrolide/azalide	Clarithromycin Erythromycin Azithromycin	15 mg/kg/day orally 30-50 mg/kg/day IV or orally 10 mg/kg × 1 day (× 2 days if parenteral), and then 5 mg/kg days 2-5 IV or orally	0.5-1 g orally once or twice daily 500 mg IV or orally every 6 to 8 hr 500 mg × 1 day (× 2 days if parenteral), and then 250 mg days 2-5 IV or orally
Fluoroquinolones[c]	Moxifloxacin	–	400 mg IV or orally daily

	Levofloxacin Ciprofloxacin	8-20 mg/kg/day IV or orally 30 mg/kg/day IV or orally	750 mg IV or orally daily 400 mg IV every 8 hr/750 mg orally twice daily
Tetracycline[d]	Doxycycline Tetracycline HCl	2-5 mg/kg/day IV or orally 25-50 mg/kg/day orally	100 mg IV or orally twice daily –
Aminoglycosides	Gentamicin Tobramycin Amikacin Plazomicin	7.5-10 mg/kg/day IV 7.5-10 mg/kg/day IV 15-20 mg/kg/day IV	7.5 mg/kg IV daily 7.5 mg/kg IV daily 15-20 mg/kg IV daily 15 mg/kg IV daily
Carbapenems	Imipenem Meropenem Meropenem-vaborbactam Imipenem-relabactam	60-100 mg/kg/day IV 30-60 mg/kg/day IV	500-1,000 mg IV every 6 to 8 hr 500-2,000 mg IV every 6 to 8 hr 2 g/2 g IV every 8 hr 1.25 g every 8 hr
Polymyxins	Colistin Polymyxin B	2.5-5 mg/kg/day IV 15,000-30,000 units/kg/day IV	IV: 300 mg × 1, then 150 mg daily/Neb: 150 mg every 8 hr IV: 2-2.5 mg/kg × 1, then 1.25-1.5 mg/kg every 12 hr
Other	Vancomycin Linezolid Clindamycin	45-60 mg/kg/day IV 20-30 mg/kg/day IV or orally 30-40 mg/kg/day IV or orally	15-20 mg/kg IV every 8-12 hr 600 mg IV or orally every 12 hr 600 mg IV or orally every 8 hr or 450 mg orally every 6 hr

[a] Doses can be increased for more severe disease and may require modification for patients with organ dysfunction.

[b] Higher-dose amoxicillin and amoxicillin/clavulanate (eg, 90 mg/kg/day) are used for penicillin-resistant *S. pneumoniae*.

[c] Fluoroquinolones have been avoided for pediatric patients because of the potential for cartilage damage; however, they have been used for MDR bacterial infection safely and effectively in infants and children (see text).

[d] Tetracyclines are rarely used in pediatric patients, particularly in those younger than 8 years because of tetracycline-induced permanent tooth discoloration.

Community-Acquired Pneumonia

⑨ Tables 129-8 and 129-9 provide evidence-based guidelines for the treatment of CAP in adults[4] and children,[5] respectively. The bacterial causes are relatively constant, even across geographic areas and patient populations. Unfortunately, pathogen resistance to standard antimicrobials is increasing (penicillin-resistant *S. pneumoniae,* macrolide-resistant *S. pneumoniae*, etc.) and can vary geographically, necessitating careful attention by the clinician to local and regional bacterial susceptibility patterns.[78] Indiscriminate use of antimicrobials for treatment of pneumonia has contributed to the problem of antimicrobial resistance, underscoring the need for defining the optimal antibiotic regimen for each patient. Thus, initial therapy should be based on presumed antibacterial susceptibility.

9 Evidence-based empiric therapy for CAP in adults differs between outpatients, hospitalized patients, and hospitalized patients admitted to an intensive care unit (see Tables 129-8 and 129-9).[4,5] In adult outpatients, choice of therapy depends on the individual patient's risk for drug-resistant *S. pneumoniae*. Amoxicillin is the preferred treatment for patients at low risk (ie, no at-risk comorbidities). Patients who cannot receive amoxicillin should be treated with doxycycline. Macrolides (such as azithromycin) should only be used when both amoxicillin and doxycycline are contraindicated and local macrolide-resistant *S. pneumoniae* prevalence is low.[4] In patients with specific comorbidities putting them at risk for treatment failure or drug-resistant *S. pneumoniae*, either anti-pneumococcal fluoroquinolone monotherapy (such as levofloxacin or moxifloxacin) or combination therapy consisting of a β-lactam (Table 129-8) plus either a macrolide or doxycycline is indicated to ensure coverage of resistant strains.[4] Empiric therapy of CAP for inpatients differs from that of outpatients in two ways: first, it is usually IV rather than oral route of administration; and second, coverage against drug-resistant *S. pneumoniae* is given to all patients. This reflects the desire to rapidly achieve adequate systemic antimicrobial exposures and increase the likelihood of providing in vitro active therapy in patients with a higher severity of illness where the importance of early appropriate therapy is increased. In patients with severe CAP, therapy should always consist of a combination regimen with a β-lactam backbone (Table 129-8), as these regimens are associated with reduced mortality in patients with bacteremic pneumococcal pneumonia.[79-81]

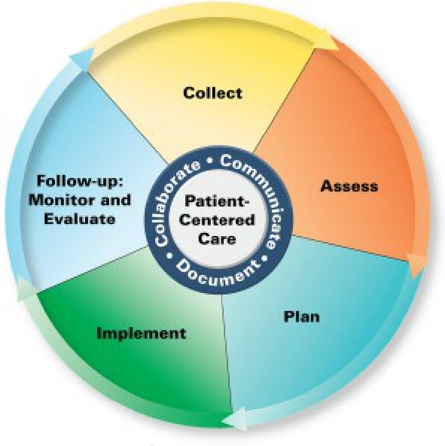
Coverage of less frequent CAP pathogens, such as MRSA and *P. aeruginosa*, may be considered in patients with specific risk factors for these pathogens.[4] Patients with a positive respiratory culture for MRSA and/or *P. aeruginosa* in the past year should receive empiric coverage for that respective pathogen.[4] Respiratory cultures and/or nasal MRSA PCR tests should be obtained in these patients before antibiotic therapy is administered. The empiric MRSA and/or *P. aeruginosa* coverage should be discontinued in 48 hours if these test results are negative for these pathogens and the patient is clinically improving. Patients who have been hospitalized in the past 90 days who also received IV antibiotics are at increased risk for both MRSA and *P. aeruginosa*. Patients meeting this criteria who have non-severe cap should have cultures and nasal MRSA PCR tests performed. Antibiotics covering MRSA and/or *P. aeruginosa* should be added only if these pathogens are identified. Patients who have been hospitalized in the past 90 days who also received IV antibiotics admitted with severe CAP should receive both empiric MRSA and *P. aeruginosa* coverage and have cultures performed. The MRSA and *P. aeruginosa* coverage should be discontinued after 48 hours if culture results are negative and the patient is clinically improving.[4]

Additional treatment considerations for adult patients with CAP include whether to provide coverage for influenza or SARS-CoV-2 and whether adjunctive corticosteroids are necessary. Nucleic acid amplification testing for influenza should be obtained when influenza and/or SARS-CoV-2 is circulating in the community.[4] Treatment with a neuraminidase inhibitor (such as oseltamivir or peramivir) should be administered only if influenza testing is positive. Adjunctive corticosteroids should only be given to patients with septic shock that is refractory to fluid resuscitation and vasopressor support.[4]

Similar to adult patients, empiric antibiotic regimens for CAP in pediatric patients differ between the outpatient and inpatient setting. However, in pediatric patients, choice of empiric therapy is more dependent on patient age group and immunization status rather than comorbidity. For outpatients, choice of therapy is predominantly based on age group and suspected etiology (ie, typical vs atypical bacteria; viral). Among inpatients, those fully immunized against *S. pneumoniae* and *H. influenzae* type B may be treated with a penicillin antibiotic with or without macrolide for typical coverage as indicated based on clinical suspicion for atypical pneumonia.[5] Empiric regimens in unimmunized patients or in areas with a high prevalence of penicillin-resistant *S. pneumoniae* should consist of third-generation cephalosporin (such as ceftriaxone).[5] Similar to CAP in adults, MRSA is sometimes the causative pathogen. Addition of MRSA coverage (with vancomycin or linezolid) should be considered when clinical suspicion is high (post-viral pneumonia, necrotizing/cavitary radiographic findings).[5]

Patient Care Process

Patient Care Process for Pneumonia



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, pregnancy, drug allergies)
- Patient medical history including comorbid conditions, previous infections, previous hospitalization, and current or recent residence in a nursing facility
- Social history (including tobacco/ethanol/drug use)
- Current and past medications, particularly antimicrobials, immune suppressants, and chemotherapy
- Subjective data
  - Patient-reported risk factors for pneumonia (Table 129-5)
  - Patient-reported pneumonia signs/symptoms (Table 129-6)
  - Timing/location of symptom onset (ie, community vs hospital; time since onset)
- Objective data
  - Temperature, blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight, O_2-saturation, ventilator settings if applicable
  - Pertinent respiratory physical exam findings (Table 129-6)
  - Diagnostic procedures (such as chest imaging)
  - Labs including CBC and differential, basic metabolic panel, blood gases, and lactate (if sepsis suspected)
  - Current and previous microbiology results including antimicrobial susceptibility when available

Assess

- Likelihood of pneumonia based on history of present illness, physical exam, imaging, and laboratory and microbiologic data
- Severity of illness and mortality risk based on hemodynamics, respiratory status, presence of organ failure, severity score(s) if CAP
- Most likely pathogens and potential for antimicrobial resistance based on age, comorbidities, clinical presentation and diagnostics, pneumonia type (ie, CAP vs HAP vs VAP vs aspiration—Table 129-5), local epidemiology and antimicrobial resistance patterns, previous infections and antibiotic exposure

Plan

- Empiric antimicrobial regimen based on likely pathogen(s) and mortality risk
  - Include drug(s), route of administration, dose, frequency, and duration (Tables 129-8 to 129-10)
- Appropriate monitoring parameters for efficacy, toxicity, and potential modification of therapy (ie cultures or other tests for etiology when indicated)
  - Include timing (cultures preferably obtained before antimicrobials administered) and frequency
- Provider education including rationale and evidence for recommendation
- Patient education including counseling points/monitoring for efficacy and safety

Implement*

- Clearly and professionally communicate recommendations to prescribers, healthcare team, and/or patient
- Determine consensus treatment plan as an interdisciplinary team
- Follow-up to ensure accurate/appropriate implementation of consensus treatment plan (antimicrobial therapy, diagnostics, and monitoring)

Follow-Up: Monitor and Evaluate

- Efficacy monitoring including improvement/resolution of signs/symptoms, physiologic and laboratory data with focus on indicators of infection (temperature, WBC, etc.), respiratory status (RR, oxygenation, ventilator settings), and organ failure/sepsis
- Safety monitoring (including SCr and urine output for nephrotoxicity, etc.)
- Microbiologic cultures and diagnostic tests for etiology
- Assess whether therapy can be narrowed, should be broadened, or requires change based on above monitoring considerations
- When possible, change empiric therapy to pathogen-directed therapy (Table 129-11)
- Design and implement new plan and continual monitoring as needed/appropriate

**Collaborate with patient, caregivers, and other healthcare professionals.*

TABLE 129-11

Directed Antimicrobial Therapy for Common Pneumonia Pathogens in Adult Patients

Pathogen	Preferred Antibiotic Therapy	Alternative Antibiotic Therapy
Penicillin-susceptible *S. pneumoniae* (MIC ≤ 2 mg/L)	Ampicillin, amoxicillin, penicillin G	Ceftriaxone, cefotaxime, macrolide, levofloxacin, moxifloxacin, doxycycline, clindamycin, vancomycin
Penicillin-resistant *S. pneumoniae* (MIC > 2 mg/L)	Ceftriaxone, cefotaxime, levofloxacin, moxifloxacin	High-dose amoxicillin (3 g/day), linezolid, clindamycin, vancomycin
Non-β-lactamase-producing *H. influenzae*	Ampicillin (IV), amoxicillin	Fluoroquinolone, doxycycline, azithromycin, clarithromycin
β-Lactamase-producing *H. influenzae*	Ceftriaxone, cefotaxime, ampicillin-sulbactam, amoxicillin-clavulanate	Fluoroquinolone, doxycycline, azithromycin, clarithromycin
Mycoplasma pneumoniae	Macrolide, doxycycline	Fluoroquinolone
Chlamydophila pneumoniae	Macrolide, doxycycline	Fluoroquinolone
Legionella pneumophila	Fluoroquinolone or azithromycin	Doxycycline
MSSA	Cefazolin, antistaphylococcal penicillin	Clindamycin, vancomycin
MRSA	Vancomycin, linezolid	Telavancin, ceftaroline, quinupristin/dalfopristin, clindamycin, sulfamethoxazole/trimethoprim
P. aeruginosa	Antipseudomonal β-lactam[a] or fluoroquinolone[b] based on antimicrobial susceptibility testing results. Can consider adding aminoglycoside if patient in septic shock or at high mortality risk	IV colistin or polymyxin B + inhaled colistin for isolates resistant to all preferred therapies
Acinetobacter spp.	Carbapenem OR ampicillin-sulbactam based on antimicrobial susceptibility testing results	IV colistin or polymyxin B + inhaled colistin for isolates resistant to all preferred therapies
Extended-spectrum β-lactamase-producing gram-negative bacilli	Carbapenem	Piperacillin-tazobactam or cefepime potential options depending on susceptibility/adequate dosing
Carbapenem-resistant organisms	New β-lactam/β-lactamase inhibitors[c] based on antimicrobial susceptibility testing OR IV colistin or polymyxin B + inhaled colistin	

[a] Antipseudomonal β-lactam: piperacillin/tazobactam, cefepime, ceftazidime, meropenem, imipenem/cilastatin, doripenem, aztreonam.

[b] Antipseudomonal fluoroquinolone: ciprofloxacin and levofloxacin

[c] New β-lactam/β-lactamase inhibitors: ceftazidime/avibactam, meropenem/vaborbactam, ceftolozane/tazobactam.

MIC, minimum inhibitory concentration; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-sensitive *Staphylococcus aureus*; *PCN,* penicillin.

Hospital-Acquired and Ventilator-Associated Pneumonia

⑨ Because HAP and VAP have a distinctive epidemiology compared with CAP, empiric antimicrobial regimens for HAP and VAP differ greatly from those for CAP (Table 129-8). Despite this, selection of therapy is based on many of the same principles. As with CAP, knowledge of the local pathogen and antibiotic resistance distribution is important. Antibiotic resistance patterns can vary greatly between institutions in the same city and even within the same institution between hospital units. Because of this, use of institution-specific antibiograms is highly recommended. These antibiograms should ideally also contain separate susceptibility data specific to the ICU population.[6] Along with local susceptibility, patient-specific factors should weigh heavily in the choice of empiric therapy. Individual risk factors for infection with MRSA and MDR gram-negative bacilli are particularly important in HAP and VAP, as is severity of illness and mortality risk.

The vast majority of HAP cases are caused by gram-negative bacilli, predominantly *P. aeruginosa* and the Enterobacteriaceae, or *S. aureus*.[6] As such, all empiric HAP regimens should consist of at least one antibiotic with coverage against these pathogens, usually an antipseudomonal, antistaphylococcal β-lactam (such as piperacillin/tazobactam or cefepime) or an antipseudomonal, antistaphylococcal fluoroquinolone (such as levofloxacin).[6] While aminoglycosides are useful in treating gram-negative pneumonia in combination with another gram-negative-active antibiotic, they should not be used as monotherapy in pneumonia given the lack of data supporting their use in this manner. Patients contracting the pneumonia in a hospital or hospital unit with an MRSA prevalence of 20% or greater should also receive MRSA coverage with either vancomycin or linezolid.[6] Patients with MDR HAP risk factors, such as receipt of IV antibiotics in the past 90 days or structural lung disease, should also receive MRSA coverage in addition to a second antipseudomonal agent to cover for MDR gram-negative bacilli. An empiric antibiotic regimen containing dual pseudomonal and MRSA coverage is also indicated in patients at high risk of mortality, such as those requiring mechanical ventilation as a result of their pneumonia and those in septic shock.[6] This approach is taken to maximize the likelihood of early effective therapy in those patients where the consequences of delayed appropriate therapy in the event the pathogen is resistant to the empiric regimen are greatest.

Empiric antibiotic regimens for patients with VAP are similar to patients with HAP. In patients with no MDR VAP risk factors, who contracted VAP in a unit with a low prevalence of both MRSA (less than 10%-20%) and of gram-negative bacilli resistance (<10% to an antibiotic being considered for use), monotherapy with an antipseudomonal antibiotic with staphylococcal coverage may be used.[6] Higher MRSA prevalence would indicate the addition of vancomycin or linezolid. Likewise, more than 10% resistance to all antibiotics being considered for gram-negative monotherapy would indicate the need for double antipseudomonal coverage (Table 129-8).[6] Patients at risk for MDR VAP, including those receiving IV antibiotics in previous 90 days, those in septic shock, those with VAP onset after 5 or more days of hospitalization, and those with acute respiratory distress syndrome or receiving renal replacement therapy preceding VAP onset should also receive double pseudomonal and MRSA coverage.[6]

Pathogen-Directed Antimicrobial Therapy

⑩ Tailoring antimicrobial therapy based on diagnostic test results and patient clinical status is an important aspect of the pharmacotherapy of pneumonia. Utilizing a pathogen-directed antimicrobial regimen can optimize patient outcome using evidence-based antimicrobials for a particular pathogen. It can also mitigate potential negative impacts of ongoing broad-spectrum antimicrobial use, including adverse drug reactions, *C. difficile* infection, and development of further MDR infection.[82-84] When tailoring antimicrobial therapy, it is important to consider both diagnostic test results (chest imaging, Gram stain, respiratory cultures), and patient clinical factors (hemodynamics, temperature, respiratory status, white blood cell counts/differential). In patients who are clinically stable with signs of improving infection, narrowing of therapy should be considered, especially if culture results have identified a likely pathogen with associated susceptibility pattern.[6] Recommendations for directed therapy of common pneumonia pathogens can be found in Table 129-11.

Directed Therapy of Important Gram-Positive Pathogens

⑩ Directed therapy for *S. pneumoniae,* the most common bacterial cause of CAP, primarily depends on penicillin susceptibility. For isolates considered susceptible to intravenous penicillin by the CLSI (MIC ≤ 2 mg/L), a narrow-spectrum penicillin such as penicillin, ampicillin, or amoxicillin is preferred.[4] Alternatively, a cephalosporin antibiotic may be used, or in the case of a severe β-lactam allergy, either a macrolide or antipneumococcal fluoroquinolone (Table 129-11).[4] For penicillin-resistant strains, a third-generation cephalosporin or fluoroquinolone is preferred (Table 129-11). High-dose amoxicillin (3 g/day) may be used for penicillin-intermediate strains (MIC = 4 mg/L).[4] High-dose amoxicillin has efficacy in these situations because resistance of *S. pneumoniae* to penicillins is conferred through a change in penicillin-binding protein resulting in decreased affinity of the antibiotic for the binding site. In the case of penicillins and *S. pneumoniae*, this can be overcome by more aggressive dosing that maximizes achievement of adequate time drug concentration is in excess of the MIC (*t*>MIC) despite the elevated MIC.[85]

Treatment of *S. aureus* pneumonia is dependent on whether the strain exhibits methicillin resistance. Treatment with an antistaphylococcal penicillin, such as oxacillin, nafcillin, or dicloxacillin, is preferred by the CAP guidelines for methicillin-susceptible strains.[4] Cefazolin is an alternative for methicillin-susceptible strains with fewer clinical data in pneumonia. However, it is an equivalent alternative to an antistaphylococcal penicillin on the basis of data from *S. aureus* bacteremia suggesting equivalence or even superiority.[86] Clindamycin or vancomycin may also be used, although these agents are not preferred for treatment of MSSA infections.[87] The treatment of choice for MRSA pneumonia is either vancomycin or linezolid, which are considered equivalent by infectious Diseases Society of America (IDSA) guidelines.[88-90] Vancomycin is often preferred over linezolid in clinical practice to preserve linezolid susceptibility for infections for which linezolid is one of the few remaining treatment options, such as infections caused by vancomycin-resistant enterococci (VRE). Telavancin, while FDA-approved for HAP/VAP caused by *S. aureus*, is often reserved for alternate therapy due to concerns of nephrotoxicity and potentially increased mortality in the subgroup of patients with a creatinine clearance less than 30 mL/min (0.5 mL/s). Additional alternatives for MRSA pneumonia include quinupristin-dalfopristin, ceftaroline, sulfamethoxazole-trimethoprim, and clindamycin. However, clinical evidence for these alternative options remains limited.[91-93]

Directed Therapy of Important Gram-Negative Pathogens

⑩ For *H. influenzae*, the most common gram-negative cause of CAP, the choice of directed therapy is dependent on whether the strain is β-lactamase producing. Non-β-lactamase-producing strains may be treated with ampicillin (IV) or amoxicillin (oral).[4] A third-generation cephalosporin (such as ceftriaxone) is the treatment of choice for β-lactamase-producing strains. Alternative therapy for *H. influenzae* includes fluoroquinolone, doxycycline, azithromycin, or clarithromycin.[4] Azithromycin is generally preferred to clarithromycin. A larger proportion of *H. influenzae* strains are susceptible to azithromycin relative to clarithromycin and azithromycin has a more favorable drug interaction profile.[94,95]

P. aeruginosa is a notoriously antibiotic-resistant pathogen that utilizes a variety of mechanisms of resistance, resulting in variable susceptibility patterns. Because of this, directed therapy against *P. aeruginosa* pneumonia is highly dependent on antimicrobial susceptibility results. When susceptible, all antipseudomonal agents recommended for empiric therapy are considered equivalent with respect to clinical outcomes in pneumonia.[6] The exception to this is the aminoglycosides, which are not recommended as monotherapy against *P. aeruginosa* pneumonia. Despite equivalence of most antibiotics in this setting, piperacillin-tazobactam, cefepime, and ceftazidime are generally preferred when susceptible. This is to preserve susceptibility of carbapenems, newer β-lactam/β-lactamase inhibitors, and fluoroquinolones for use in more resistant infections. Another consideration in the directed therapy of *P. aeruginosa* is the utility of combination therapy. Patients receiving monotherapy and combination therapy generally have similar outcomes.[6] However, combination therapy may be associated with reduced mortality in patients with septic shock.[96] Directed combination therapy against *P. aeruginosa* only is recommended in patients in septic shock or at high risk of mortality at the time antimicrobial susceptibility testing results become available.[6]

Enterobacterales, particularly *K. pneumoniae* and *E. coli*, are common causes of both HAP and VAP. Although generally susceptible to the gram-negative active agents recommended for empiric therapy of HAP and VAP, Enterobacteriaceae-producing extended-spectrum β-lactamases (ESBL) capable of hydrolyzing many of the β-lactams commonly used for empiric therapy have become increasingly common.[97-99] Because this diverse family of β-lactamases each has variable affinity for different β-lactams, susceptibility to each β-lactam agent can vary depending on the enzyme (ie, CTX-M, TEM, SHV).[100] Further complicating this is the inoculum effect, whereby β-lactams seemingly susceptible in vitro are hydrolyzed in vivo in the presence of a high-inoculum of ESBL-producing organism.[101] This variable susceptibility has resulted in debate regarding the treatment of choice for these infections. Although the limited evidence from observational studies did not demonstrate superiority of carbapenems over piperacillin/tazobactam or cefepime when the organism is susceptible to these agents, carbapenems are often considered the treatment of choice for serious ESBL infections such as pneumonia.[6] Piperacillin/tazobactam was not as effective meropenem for ceftriaxone-resistant *E. coli* or *K. pneumoniae* bloodstream infections.[102] Based on this, carbapenems will likely continue to be considered the treatment of choice for serious ESBL infections. If piperacillin/tazobactam or cefepime are utilized, it is important to ensure that the isolate is considered fully susceptible by the Clinical and Laboratory Standards Institute (CLSI) and that aggressive dosing strategies to ensure optimal $t >$ MIC are employed.

While initially thought of as reliable, last-line antibiotics for resistant gram-negative infections, resistance to carbapenems due to a variety of mechanisms has emerged. Until recently, few antibiotics retained activity against these organisms, resulting in a resurgence in the use of older, more toxic agents such as the polymyxins (colistin, polymyxin B). Availability of three new β-lactam/β-lactamase inhibitor combinations, ceftolozane-tazobactam, ceftazidime-avibactam, and meropenem-vaborbactam has provided hope for these infections. Ceftazidime/avibactam and meropenem/vaborbactam have in vitro activity against most carbapenem-resistant Enterobacteriaceae (CRE) acquiring resistance via carbapenemase enzymes.[103,104] Although ceftolozane-tazobactam does not have activity against carbapenemase-producing strains, it is active against many carbapenem-resistant *P. aeruginosa* strains where the primary mechanism of carbapenem resistance is change in cell permeability and/or efflux pumps.[105] Clinical data suggest that these new antimicrobials may be superior and less toxic relative to colistin- and/or aminoglycoside-containing regimens.[106–108,119] Coupled with favorable in vitro susceptibility data it seems reasonable to prefer these novel agents to more toxic polymyxin-containing regimens when the isolate is susceptible. Additional new antibiotic therapies with in vitro activity against many MDR pathogens that commonly cause lower respiratory tract infections and varying levels of clinical evidence include cefiderocol, plazomicin, imipenem-cilastatin-relebactam, and eravacycline. For infections that remain resistant to all other available antibiotics, treatment with inhaled polymyxins or aminoglycosides are recommended.[6] Inhaled antibiotics should be given with systemic antibiotics to which the pathogen is susceptible (ie, if only susceptible to colistin, give both inhaled and IV colistin).

Directed Therapy of Important Atypical Pathogens

⑩ Treatment of pneumonia caused by atypical bacteria, including *C. pneumoniae*, *M. pneumoniae*, and *L. pneumophila*, generally consists of either a fluoroquinolone, macrolide, or doxycycline. For *C. pneumoniae* and *M. pneumoniae*, macrolides or doxycycline are preferred agents.[4] Fluoroquinolones or azithromycin is preferred over doxycycline for *Legionella* pneumonia due to the relative paucity of data involving doxycycline for this infection.[4]

Antimicrobial Pharmacokinetic/Pharmacodynamic Considerations

Antimicrobial pharmacokinetics/pharmacodynamics (PK/PD) is an important aspect of optimal antimicrobial therapy for pneumonia. Antibiotic concentrations in respiratory secretions in excess of the pathogen MIC are necessary for successful treatment of pulmonary infections.[109] Thus, ability of an antimicrobial to penetrate into pulmonary secretions is important and must be factored into antimicrobial selection and dosing for pneumonia. The ability of a drug to penetrate respiratory secretions depends on multiple physicochemical factors, including molecular size, lipid solubility, and degree of ionization at serum and biologic fluid pH and the extent of protein binding. Studies evaluating antibiotic concentrations in the pulmonary epithelial lining fluid (ELF) indicate that β-lactams, glycopeptide, and aminoglycosides tend to have ELF to plasma antibiotic concentration ratios less than 1. In contrast, macrolides, fluoroquinolones, and linezolid tend to have ELF to plasma antibiotic concentration ratios much greater than 1. Thus, the latter agents penetrate and concentrate into the ELF to a greater extent.[109]

Although β-lactams, glycopeptides, and aminoglycosides have less extensive ELF penetration, carefully constructed dosing schemes based on PK/PD principles allow these agents to be effective in treating lower respiratory tract infections. Although evidence is conflicting, dosing guided by PK/PD principles may reduce mortality and improve clinical outcome in patients with pneumonia.[6] The use of strategies maximizing antibiotic PK/PD to select antibiotic dosing for HAP and VAP is recommended by the IDSA guidelines.[6] This includes weight-based initial dosing of vancomycin and aminoglycosides followed by measurement of serum antibiotic concentrations to adjust doses through antibiotic therapeutic drug monitoring (TDM) and use of extended or continuous infusion of β-lactams. Dosing and TDM of vancomycin for pneumonia should target achievement of a vancomycin area under the concentration-time curve (AUC) 400-600 mg*hr/L early in the course of therapy.[110,111] This will maximize achievement of AUC/MIC ratios > 400 for *S. aureus* isolates with an MIC ≤ 1 mg/L. Clinical practice guidelines recommend this should preferably be achieved via AUC monitoring.[112] Alternatively, this may be achieved by targeting vancomycin trough concentrations of 15-20 mg/L (10.4-13.8 μmol/L) as surrogate for AUC > 400 mg*h/L, although this approach leads to supratherapeutic AUC in a large proportion of patients and a resulting increased risk of vancomycin-associated nephrotoxicity.[13,120] The preferred aminoglycoside dosing strategy for pneumonia, when patient renal function permits, is high-dose once-daily administration. This approach maximizes the AUC:MIC and peak:MIC ratios for efficacy while allowing undetectable serum trough concentrations for a period of time to minimize nephrotoxicity.[113,114] Aminoglycoside peak:MIC ratios ≥ 10 are typically targeted clinically for pneumonia. We refer the reader to Chapter e126, "Laboratory Tests to Direct Antimicrobial Pharmacotherapy" and Chapter 127 for more in-depth discussion of antibiotic PK/PD concepts.

PATIENT MONITORING, THERAPY MODIFICATION, AND DURATION OF THERAPY

After therapy has been instituted, appropriate clinical parameters should be monitored to ensure the efficacy and safety of the therapeutic regimen. For patients with bacterial infections of the lower respiratory tract, the time to resolution of initial presenting symptoms and the lack of appearance of new associated symptomatology are important to determine.[115] For patients with pneumonia of mild-to-moderate clinical severity, the time to resolution of cough, decreasing sputum production, and fever, as well as other constitutional symptoms of malaise, nausea, vomiting, and lethargy, should be noted. If the patient requires supplemental oxygen therapy, the amount and need should be assessed regularly. A gradual and persistent improvement in the resolution of these symptoms and therapies should be observed. Initial resolution of infection should be observed within the first 2 days of therapy and progression to complete resolution within 5 to 7 days (usually no more than 10 days). Because cultures for causative organism are rarely obtained except for more severe CAP cases, empiric therapy is typically continued for the duration of therapy provided the patient is responding adequately. When cultures are obtained, tailoring therapy to be pathogen-directed as described above is recommended. The majority of hospitalized patients with CAP should be switched from IV to oral therapy when hemodynamically stable, improving clinically as described above, have normal gastrointestinal tract function, and be able to ingest oral medications.[4] The minimum duration of therapy for CAP is 5 days, although CAP is commonly treated for 7 to 10 days.[4] When discontinuing therapy, patients should be afebrile for 48 to 72 hours and have no more than one CAP-related sign of clinical instability (ie, tachycardia, tachypnea, hypotension, hypoxia, altered mental status). Discontinuation of therapy using these criteria starting at day 5 of therapy decreases the duration of antibiotic therapy without reducing cure rates or increasing readmission in non-ICU CAP patients.[116]

For patients with HAP, substantial underlying diseases, or both, additional parameters can be followed, including the magnitude and character of the peripheral blood WBC count, chest radiograph, and blood gas determinations. Similar to patients with less severe disease, some resolution of symptoms should be observed within 2 days of instituting antibiotic therapy. If no resolution of symptoms is observed within 2 days of starting seemingly appropriate antibiotic therapy or if the patient's clinical status is deteriorating, the appropriateness of initial antibiotic therapy should be critically reassessed. The patient should be evaluated carefully for deterioration of underlying concurrent disease(s). Additionally, the clinician should consider the possibility of changing the initial antibiotic therapy to expand antimicrobial coverage not included in the original regimen if the patient's clinical status is worsening or failing to improve after 48 to 72 hours of therapy. The results of initial and follow-up diagnostic tests, such as respiratory cultures, should also be used alongside clinical response to streamline therapy. De-escalation of antibiotic therapy to be more narrow spectrum in patients with HAP/VAP is strongly recommended. This approach may not affect clinical outcomes while reducing excess antibiotic use.[6] The recommended duration of therapy for HAP/VAP is 7 days, as the clinical benefit of longer durations of therapy (≥10 days) is not clear based on available clinical evidence.[6] Serum procalcitonin concentrations in combination with clinical response criteria can be used in the decision to discontinue antibiotic therapy.[6]

Prevention of Pneumonia

Prevention of some cases of pneumonia is possible through the use of vaccines and medications against selected infectious agents. Polyvalent polysaccharide vaccines are available for two of the leading causes of bacterial pneumonia, *S. pneumoniae* and *H. influenzae* type b. Children should be vaccinated against *S. pneumoniae*, *H. influenzae* type b, pertussis, and influenza while caregivers for infants less than 6 months should also be vaccinated against influenza and pertussis. Immune prophylaxis for RSV is only recommended for high-risk infants during RSV season. To minimize the risk of developing VAP, healthcare providers should seek to minimize colonization of the aerodigestive tract, prevent aspiration (head raised 45 degrees), and limit the length of mechanical ventilation of patients.[60] (See Chapter 131 for a full discussion of influenza postexposure prophylaxis and Chapter 147, "Vaccines, Toxoids, and Other Immunobiologics" for vaccines.)[117]

AUC	area under the concentration-time curve
BAL	bronchoalveolar lavage
CAP	community-acquired pneumonia
CLSI	Clinical and Laboratory Standards Institute
Cmax	maximum concentration
COPD	chronic obstructive pulmonary disease
CRE	carbapenem-resistant Enterobacteriaceae
ELF	epithelial lining fluid
FEV_1	forced expiratory volume in the first second of expiration
GOLD	Global Initiative for Chronic Obstructive Lung Disease
HAP	hospital-acquired pneumonia
HIV	human immunodeficiency virus
LABA	long-acting β-receptor agonist
LAMA	long-acting muscarinic antagonist
MDR	multidrug-resistant
MIC	minimum inhibitory concentration
MRSA	methicillin-resistant *Staphylococcus aureus*
NAC	*N*-acetyl cysteine
PCR	polymerase chain reaction
PDE4	phosphodiesterase 4
PK-PD	pharmacokinetics/pharmacodynamics
RSV	respiratory syncytial virus
SARS	severe acute respiratory syndrome

SARS-CoV	severe acute respiratory syndrome coronavirus
TDM	therapeutic drug monitoring
VAP	ventilator-associated pneumonia
VRE	vancomycin-resistant enterococci
WBC	white blood cell

SELF-ASSESSMENT QUESTIONS

1. In the absence of a complicating bacterial infection, which of the following is the most appropriate approach to treating acute bronchitis?
    A. Prescribing broad-spectrum antibiotics
    B. Routinely recommending non-prescription cough and cold preparations
    C. Providing symptomatic and supportive care
    D. Discouraging hydration and bed rest
2. Which of the following is true regarding chronic bronchitis?
    A. The majority of patients who suffer from chronic bronchitis have a negative smoking history.
    B. *N*-acetylcysteine should be routinely prescribed to treat associated bronchospasm.
    C. Given the low incidence of bacterial resistance, broad-spectrum antibiotics are rarely employed.
    D. During acute exacerbations, the use of antimicrobial is controversial; however, patients with prominent symptoms may benefit.
3. Which of the following is the most common cause of bronchiolitis?
    A. Respiratory syncytial virus
    B. Parainfluenza virus
    C. Mycoplasma
    D. Adenovirus
4. Which of the following statements is true regarding the treatment of bronchiolitis?
    A. The routine use of systemic corticosteroids should be encouraged.
    B. The use of aerosolized albuterol is associated with significant improvement in a majority of patients.
    C. Due to its clinical efficacy, ribavirin should be routinely prescribed.
    D. Hypertonic saline has proven efficacy after 1 day of use.
5. Community-acquired bacterial pneumonia is most commonly caused by:

A. *Staphylococcus aureus*

B. *Listeria monocytogenes*

C. *Legionella* species

D. *Streptococcus pneumoniae*

6. Which of the following would be the most appropriate empiric therapy for hospital-acquired pneumonia in a patient who has not received antibiotics in the past 90 days in a hospital with an MRSA prevalence of 10%?

A. Ceftriaxone

B. Vancomycin

C. Piperacillin/tazobactam

D. Cefepime + vancomycin

7. Which of the following pathogens should be highly suspected when prescribing empiric antimicrobial therapy to a newborn?

A. *Mycoplasma*

B. Group A *Streptococcus*

C. Group B *Streptococcus*

D. *Pseudomonas*

8. Which of the following is a risk factor for multidrug-resistant hospital-acquired pneumonia?

A. Receipt of intravenous chemotherapy in the past 90 days

B. Receipt of corticosteroids in the past 90 days

C. Receipt of intravenous antibiotics in the past 90 days

D. Receipt of highly active antiretroviral therapy (HAART) in the past 90 days

9. Which of the following would be the most appropriate therapy for the treatment of *Mycoplasma* pneumonia in a patient with compliance issues and currently receiving theophylline?

A. Erythromycin

B. Azithromycin

C. Clindamycin

D. Clarithromycin

10. Which of the following would be the most preferred antimicrobial agents in the treatment of aspiration pneumonia in a hospitalized patient with a necrotizing lesion on chest radiograph?

A. Clindamycin and ceftriaxone

B. Piperacillin/tazobactam and vancomycin

C. Cefepime

D. Ceftriaxone

11. Which of the following is NOT a risk factor for multidrug-resistant ventilator-associated pneumonia?

    A. Receipt of intravenous antibiotics in the past 90 days

    B. Acute respiratory distress syndrome preceding VAP onset

    C. Receipt of a blood transfusion in the past 90 days

    D. Receipt of renal replacement therapy prior to VAP onset

12. Which of the following would be appropriate empiric antibiotic therapy for a patient being admitted to the intensive care unit requiring mechanical ventilation due to community-acquired pneumonia?

    A. Ceftriaxone

    B. Ceftriaxone + azithromycin

    C. Levofloxacin

    D. Levofloxacin + azithromycin

13. Which of the following is appropriate empiric therapy for a patient with VAP who is currently in septic shock?

    A. Vancomycin + piperacillin/tazobactam

    B. Piperacillin/tazobactam + tobramycin

    C. Linezolid + ertapenem + ciprofloxacin

    D. Vancomycin + cefepime + tobramycin

14. Which of the following is considered a first-line antibiotic therapy for ESBL *E. coli* pneumonia?

    A. Ertapenem

    B. Tobramycin

    C. Cefepime

    D. Ceftriaxone

15. Which of the following is considered a first-line antibiotic therapy for MRSA pneumonia?

    A. Daptomycin

    B. Clindamycin

    C. Linezolid

    D. Telavancin

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** Acute bronchitis is typically self-limiting and management involves symptomatic and supportive care. Antipyretics/analgesics, increasing fluid intake, and resting are the primary management options. Patients may use non-prescription cough and cold products; however, there is limited

evidence supporting their efficacy. Routine use of antibiotics also has limited benefit.

2. **D.** Acute exacerbations of chronic bronchitis may benefit from antimicrobial therapy if patients have two of the three symptoms: increase in shortness of breath, increase in sputum, and increase in purulent sputum (see Fig. 129-1). Use of antimicrobials should also take into account risk factors and severity of symptoms. Inhaled NAC can cause bronchospasms, and bacterial resistance to antibiotics is increasing so broad-spectrum antibiotics are becoming first-line.

3. **A.** Respiratory syncytial virus (RSV) is the most common cause of bronchiolitis accounting for up to 75% of cases.

4. **D.** Management of bronchiolitis includes symptomatic and supportive care options based on the severity of symptoms. Hypertonic (3%) saline has been proven to be safe and effective after 1 day of use; however, there is debate regarding it shortening the length of hospital stay. The use of bronchodilators and steroids have not shown significant benefit and may cause harm. Ribavirin is not recommend for routine use but may be considered for severely ill patients.

5. **D.** *Streptococcus pneumoniae* is the most common cause of community-acquired-bacterial pneumonia in both children and adults according to numerous epidemiologic studies.

6. **C.** Coverage for MSSA and single antipseudomonal coverage is recommended in patients with HAP who are at low mortality risk (no septic shock or mechanical ventilation secondary to pneumonia), have no MDR risk factors (IV antibiotics in the past 90 days or structural lung disease), and a hospital MRSA prevalence < 20%. Only choice C provides coverage for both MSSA and *P. aeruginosa* without providing unnecessary MRSA coverage.

7. **C.** Group B *Streptococcus* is the most common cause of bacterial pneumonia in neonates. This is because Group B *Streptococcus* is a normal colonizing bacteria of the vaginal epithelium in many women.

8. **C.** Only IV antibiotics in the past 90 days is a consistently proven risk factor for multidrug-resistant HAP among the listed choice. The other choices may result in immune-compromise but are not risk factors for multidrug-resistant pathogens.

9. **B.** The recommended treatment of *Mycoplasma* pneumonia is a macrolide. Azithromycin is preferred, especially in this case, because it avoids a drug-drug interaction with theophylline. Both clarithromycin and erythromycin have been shown to increase serum concentrations of theophylline and increase the risk of theophylline toxicity.

10. **B.** Coverage *P. aeruginosa* is required in this patient because the aspiration occurred in the hospital. Coverage of MRSA is also required because the hospital MRSA prevalence is unknown at this time. Anaerobic coverage is indicated in patients with aspiration pneumonia who have signs of anaerobic pneumonia on imaging, such as a necrotizing lesion or abscess. Piperacillin-tazobactam plus vancomycin is the only answer choice that provides the recommended spectrum of activity for this patient.

11. **C.** Receipt of IV antibiotics in the 90 days preceding VAP, acute respiratory distress syndrome preceding VAP, and receipt of renal replacement therapy prior to VAP onset are all MDR VAP risk factors. Receipt of a blood transfusion is not a risk factor for MDR bacterial infection.

12. **B.** The patient has severe CAP because they require mechanical ventilation due to the CAP. Empiric treatment of severe CAP should consist of combination therapy with a β-lactam backbone such as choice B.

13. **D.** Empiric therapy for patients with VAP who are currently in septic shock should cover MRSA and double cover *P. aeruginosa* because septic shock is considered an MDR risk factor in patients with VAP. Choice D is the only answer choice that provides this coverage.

14. **A.** Carbapenems are considered first-line therapy for serious ESBL infections including ESBL pneumonia.

15. **C.** Vancomycin and linezolid are the only antibiotics that are considered first-line for MRSA pneumonia because they are the most evidence-based options.

Chapter 130: Upper Respiratory Tract Infections

Grace C Lee; Brady L Frei; Christopher R Frei

KEY CONCEPTS

KEY CONCEPTS

① Many upper respiratory tract infections are due to viral etiologies and will resolve spontaneously without pharmacologic therapy.

② The most common bacterial causes are *Streptococcus pneumoniae* (acute otitis media and acute rhinosinusitis) and group A β-hemolytic *Streptococcus* (acute pharyngitis).

③ Vaccination against influenza and pneumococcus may decrease the risk of acute otitis media.

④ Distinguishing between viral and bacterial causes for upper respiratory tract infections may be difficult, and antimicrobials are often prescribed inappropriately leading to antimicrobial resistance.

⑤ When antimicrobials are indicated, amoxicillin or amoxicillin-clavulanate is first-line for acute otitis media, amoxicillin-clavulanate for acute rhinosinusitis, and amoxicillin or penicillin for acute pharyngitis.

⑥ For acute otitis media, high-dose amoxicillin (80-90 mg/kg/day in two divided doses) is recommended.

BEYOND THE BOOK

Watch the videos entitled “What is an upper respiratory infection (URI)?”, “What is sinusitis?”, and “Pharyngitis” in Khan Academy. These videos provide an overview of common UPI. Compare and contrast infectious etiologies, diagnoses, and clinical presentation of these conditions.

INTRODUCTION

Upper respiratory tract infection is the most common reason for visits to primary care providers. There are over 25 million office visits per year for acute upper respiratory tract infections.[1] Otitis media, rhinosinusitis, and pharyngitis are the three most common upper respiratory tract infections. Although most upper respiratory tract infections typically manifest as mild illnesses, their high incidence and transmissibility places these infections as a leading cause of missed work or school days. The majority of these illnesses are caused by viruses; however, distinguishing patients with viral versus bacterial infection poses challenges as signs and symptoms are generally similar. Upper respiratory tract infections remain the leading condition for antibiotic prescribing, often inappropriately, and thereby serve as catalysts for the emergence and spread of antibiotic resistance. The prudent use of antibiotics for upper respiratory tract infections is critically important.

ACUTE OTITIS MEDIA

Acute otitis media comes from the Latin *oto-* for “ear,” *itis* for “inflammation,” and *medi-* for “middle”; otitis media, then, is an inflammation of the middle ear. There are three subtypes of otitis media: acute otitis media, otitis media with effusion, and chronic otitis media. Acute otitis media is the subtype with the greatest role for antibiotics and will be discussed in detail.

Epidemiology

Acute otitis media is primarily an infection during childhood and is the most common pediatric infection for antibiotic prescribing in the United States. There are more than 709 million cases of otitis media worldwide each year; half of these cases occur in children under 5 years of age.[2] Most cases of acute otitis media occur in young children ages 6 to 24 months. Fortunately, the incidence of acute otitis media has declined over the past two decades, and a downward trend in acute otitis media healthcare visits have been observed in children younger than 5 years of age from 2001 to 2011. The introduction of routine pneumococcal vaccinations in infants may have been a major contributor to this decline, coinciding with the introduction of the 7-valent pneumococcal conjugate vaccine (PCV-7) in 2000, that was updated with PCV-13 starting in 2010.[3]

Etiology

① Acute otitis media frequently occurs following an initial viral upper respiratory illness (eg, common cold) that often predisposes the patient to a bacterial otitis media. When comprehensive and sensitive microbiologic methods have been used in patients with a diagnosis of acute otitis media, bacteria have been found in more than 80% of cases.[4]

② Common bacterial pathogens include *Streptococcus pneumoniae*, nontypeable *Haemophilus influenzae*, and *Moraxella catarrhalis*.[5] *S. pneumoniae* and *H. influenzae* together cause up to 60% of all pediatric cases. *Staphylococcus aureus* including methicillin-resistant *S. aureus* is uncommon in children, although it is an emerging pathogen in adult.

S. pneumoniae is an important cause of acute otitis media. Among children, there has been a dramatic shift in the microbial etiology after the introduction and widespread use of the pneumococcal conjugate vaccines. Specifically, the proportion of *S. pneumoniae* cases has declined over time, and the proportion of *H. influenzae* cases has risen.[4–6]

S. pneumoniae, *H. influenzae*, and *M. catarrhalis* can all possess resistance to β-lactams. *S. pneumoniae* develops resistance through alteration of penicillin-binding proteins, whereas *H. influenzae* and *M. catarrhalis* produce β-lactamases.

Pathophysiology

Acute otitis media usually follows a viral upper respiratory tract infection that impairs the mucociliary apparatus and causes Eustachian tube dysfunction in the middle ear. The middle ear is the space behind the tympanic membrane, or eardrum. A noninfected ear has a thin, clear tympanic membrane. In otitis media, this space becomes blocked with fluid, resulting in a bulging and erythematous tympanic membrane. Acute otitis media results when bacteria from the nasopharynx enter the inflammatory fluid in the middle ear and are not cleared properly by the mucociliary system. The bacteria proliferate and cause infection. Children tend to be more susceptible to otitis media than adults because the anatomy of their Eustachian tube is shorter and more horizontal, facilitating bacterial entry into the middle ear.[7]

Clinical Presentation

Patients or caregivers frequently characterize acute otitis media as having an acute onset of otalgia (ear pain). For parents of young children, irritability and tugging on the ear are often the first clues that a child has acute otitis media. In adults, an upper respiratory tract infection or seasonal allergic rhinitis episode often predisposes the onset of acute otitis media. In adults it is usually unilateral with ear pain and muffled hearing. If the tympanic membrane is ruptured, a sudden relief of pain followed by purulent otorrhea may be reported.

The diagnosis of acute otitis media includes demonstration of fluid in the middle ear. The American Academy of Pediatrics (AAP) guidelines have stringent diagnostic criteria to ensure accurate diagnosis. Children should be diagnosed with acute otitis media if they have middle ear effusion *and* either (1) moderate-to-severe bulging of the tympanic membrane *or* new onset otorrhea not due to acute otitis externa, or (2) mild bulging of the tympanic membrane *and* onset of ear pain within the last 48 hours or intense erythema of the tympanic membrane. Middle ear effusion should be identified based on pneumatic otoscopy and/or tympanometry.[4]

The diagnoses of acute otitis media and otitis media with effusion are easily confused, and careful attention to history, signs, and symptoms is important. Otitis media with effusion is characterized by fluid in the middle ear without signs and symptoms of acute ear infection, such as pain and a bulging eardrum.[8]

CLINICAL PRESENTATION: ACUTE OTITIS MEDIA

General

- Cases of acute otitis media often follow viral upper respiratory tract infections or an exacerbation of seasonal allergic rhinitis. Nonverbal children with ear pain might hold, rub, or tug their ear. Infants might cry, be irritable, or have difficulty sleeping.

Signs and Symptoms

- Bulging of the tympanic membrane
- Reduced tympanic membrane mobility (pneumatoscopy)
- Otorrhea
- Otalgia (considered to be moderate or severe if pain lasts at least 48 hours)
- Diminished hearing
- Fever (considered to be severe if temperature is 39°C [102.2°F] or higher)
- Other signs reported include vertigo, nystagmus, and tinnitus

Data from Reference 3.

Treatment

Desired Outcomes

⑥ Treatment goals include pain management and prudent antibiotic use.

③ Pneumococcal conjugate vaccine and annual influenza vaccination should be assessed in all children according to the Advisory Committee on Immunization Practices (ACIP) schedule from the United States Centers for Disease Control and Prevention (CDC).[3] Also, because acute otitis media cases often follow influenza cases, influenza vaccination should be considered as a possible means to prevent acute otitis media.

General Approach to Treatment

The first step in treatment is to differentiate acute otitis media from otitis media with effusion or chronic otitis media, as the latter two types do not necessitate antibiotic therapy. Risk factors and disease severity of acute otitis media are assessed when considering initiation of antibiotic therapy. Amoxicillin is the mainstay of therapy and can overcome penicillin resistance, in many cases, with higher doses. The therapeutic strategy should be changed if complications develop or if symptoms fail to resolve within 3 days.

Pharmacologic Therapy

National clinical practice guidelines for diagnosis and management of acute otitis media (updated in 2013) are focused on children 6 months to 12 years of age with uncomplicated cases and without underlying conditions that may alter the natural course of the disease.[4] The decision to administer antibiotics or initially observe the patient (“watchful waiting”) depends on patient age, symptom severity, laterality, and joint decision-making.

Antibiotic therapy should be initiated for:

- Children 6 months and older with acute otitis media showing severe symptoms (ie, toxic-appearing, persistent ear pain lasting more than 48 hours, or temperature of 39°C [102.2°F] or higher)
- Children 6 months and older with acute otitis media with otorrhea
- Children 6 to 23 months of age, with bilateral acute otitis media

Observation without initial antibiotic treatment can be considered for:

- Children 6 months and older with nonsevere unilateral acute otitis media without otorrhea
- Children 24 months and older with bilateral acute otitis media without otorrhea

Initial observation (watchful waiting) should be based on joint decision-making with parents/caregivers, and must include a plan to initiate antibiotics if the child's symptoms worsen or decline within 48 to 72 hours of symptom onset.[4] The central principle is to administer antibiotics quickly when the diagnosis is certain, but to withhold antibiotics, at least initially, when the diagnosis is uncertain.

④ Antibiotic therapy for upper respiratory diseases must be balanced with possible increases in adverse drug events and increased antibiotic pressure to cause bacterial resistance. Systematic reviews and randomized controlled trials suggest a moderate benefit of antibiotics for the treatment of acute otitis media, including a marked decline in suppurative complications, and improved outcomes in both early- and late-phases.[9,10] On the other hand, rates of adverse effects, such as diarrhea and diaper rash are higher for children who receive antibiotics for acute otitis media.

There are no national guideline recommendations for the treatment of acute otitis media among adults. Data regarding the etiologies and safety of withholding antibiotics are limited for adults. Because acute otitis media is unusual among adults without underlying risk factors where complications might be significant, the general recommendation is to treat adults with empiric antibiotic therapy.[5] Choice of antibiotic regimens should be based on (1) coverage of the common bacterial pathogens (see Etiology), and (2) allergy, tolerance, previous exposure to antibiotics, costs, and resistance levels. Table 130-1 lists antibiotic recommendations for acute otitis media.

TABLE 130-1

Antibiotics and Doses for Acute Otitis Media

Antibiotic	Brand Name	Dose	Comments[a]
Initial Diagnosis			
Amoxicillin	Amoxil®	80-90 mg/kg/day orally divided twice daily	First-line
Amoxicillin-clavulanate	Augmentin®	90 mg/kg/day orally of amoxicillin plus 6.4 mg/kg/day orally of clavulanate, divided twice daily	First-line if certain criteria are present[b]
Cefdinir, Cefuroxime, Cefpodoxime	Omnicef®, Ceftin®, Vantin®	Cefdinir (14 mg/kg/day orally in 1-2 doses), Cefuroxime (30 mg/kg/day orally divided in two daily, Cefpodoxime (10 mg/kg/day orally divided in two daily doses)	Second-line or nonsevere penicillin allergy
Ceftriaxone	Rocephin®	50 mg/kg/day IM or IV once daily for 3 days	Second-line or nonsevere penicillin allergy
Failure at 48-72 Hours			
Amoxicillin-clavulanate[b]	Augmentin®	90 mg/kg/day orally of amoxicillin plus 6.4 mg/kg/day orally of clavulanate, divided twice daily	First-line
Ceftriaxone	Rocephin®	50 mg/kg/day IM or IV once daily for 3 days	First-line or nonsevere penicillin allergy

IM, intramuscular; IV, intravenous

[a] Amoxicillin-clavulanate 90:6.4 or 14:1 ratio is available in the United States; 7:1 ratio is available in Canada (use amoxicillin 45 mg/kg for one dose, amoxicillin 45 mg/kg with clavulanate 6.4 mg/kg for second dose).

[b] If a patient has received amoxicillin in the last 30 days, has concurrent purulent conjunctivitis, or has a history of recurrent infection unresponsive to amoxicillin.

Data from Reference 4.

5 Amoxicillin is the first-line therapy for most children.[4] Exceptions include: children who have received amoxicillin in the last 30 days, have concurrent purulent conjunctivitis, or have a history of recurrent infection unresponsive to amoxicillin. These patients should receive amoxicillin-clavulanate instead of amoxicillin. Patients with otitis conjunctivitis syndrome are more likely to be infected with nontypeable *H. influenzae*, hence the need for a β-lactamase inhibitor (such as clavulanate).[4] Clinicians should reassess the plan if the child's symptoms worsen or decline within 48 to 72 hours of symptom onset.[4]

High-dose amoxicillin (80-90 mg/kg/day in two divided doses) is recommended for most pediatric patients with acute otitis media. Amoxicillin has the best pharmacodynamic profile against drug-resistant *S. pneumoniae* of all available oral antibiotics. In addition, amoxicillin has a long record of safety, possesses a narrow spectrum of activity, is inexpensive, and is more palatable than other options. Higher middle ear fluid concentrations of amoxicillin, as a result of higher dosing, overcome most drug-resistant *S. pneumoniae*.[3] Its excellent efficacy against *S. pneumoniae* outweighs the issue of β-lactamase-producing *H. influenzae* and *M. catarrhalis*, against which amoxicillin may not be effective. This is because both *H. influenzae* and *M. catarrhalis* are more likely than *S. pneumoniae* to lead to a spontaneous resolution of the infection.

A patient who has received amoxicillin in the last 30 days, has concurrent purulent conjunctivitis, or has a history of recurrent infection unresponsive to amoxicillin should receive high-dose amoxicillin-clavulanate (90 mg/kg/day of amoxicillin, with 6.4 mg/kg/day of clavulanate, in two divided doses) instead of amoxicillin. Amoxicillin-clavulanate has activity against β-lactamase-producing *H. influenzae* and *M. catarrhalis* as well as drug-resistant *S. pneumoniae*.[4]

In most adults, the first-line treatment is amoxicillin-clavulanate 875 mg with clavulanate 125 mg orally twice daily. A higher dose of the amoxicillin component (2,000 mg) with clavulanate is recommended for patients with clinical or epidemiologic risk for severe infections or infections due to penicillin nonsusceptible *S. pneumoniae* (those who live in regions with >10% penicillin nonsusceptible *S. pneumoniae*, 65 years and older, immunocompromised, recent hospitalizations, or have used antibiotics in the past month).[5]

Other antibiotic choices include cefdinir, cefuroxime, cefpodoxime, and intramuscular or intravenous ceftriaxone.[4] Second-generation cephalosporins, though β-lactamase stable, are expensive, have an increased incidence of side effects, and may increase selective pressure for resistant bacteria. Furthermore, most cephalosporins do not achieve adequate middle ear fluid concentrations against drug-resistant *S. pneumoniae* for the desired duration of the dosing interval. Amoxicillin and intramuscular ceftriaxone and amoxicillin are the only antibiotics that achieve middle ear fluid concentrations above the minimal inhibitory concentration (MIC) for greater than 40% of the dosing interval. Although single doses of ceftriaxone have been used, daily doses for 3 days are recommended to optimize clinical outcomes.[4] Ceftriaxone is more expensive than amoxicillin and the intramuscular injections are painful.

Patients with a penicillin allergy can be treated with several alternative antibiotics, including a cephalosporin in patients without history of severe or type 1 penicillin allergy. Use of trimethoprim-sulfamethoxazole and erythromycin-sulfisoxazole is discouraged because of high rates of resistance. Notably, clindamycin lacks efficacy against *H. influenzae*. Cefdinir or azithromycin (Zithromax) should be the first-line antibiotic in those with penicillin allergy based on risk of cephalosporin allergy.

There is ongoing debate regarding the optimal duration of therapy for acute otitis media. Duration is based on age and severity of symptoms. Traditional recommendations call for 10 days of antibiotic therapy; however, some experts have speculated that patients can be treated for as little as 5 to 7 days. Short-course treatment is not recommended in children younger than 2 years of age.[11] In children at least 6 years of age who have uncomplicated acute otitis media, a 5- to 7-day treatment course may be used.[4]

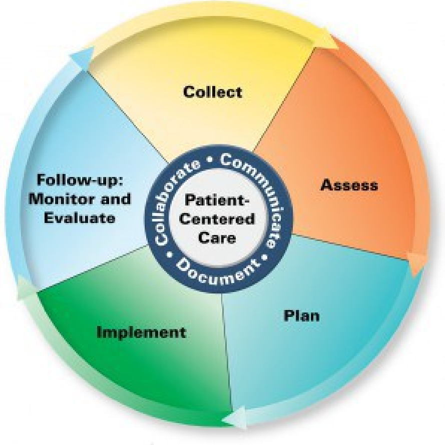
Recurrent acute otitis media is defined as at least three episodes in 6 months or four episodes in 1 year, with one episode in the preceding 6 months. Recurrent episodes are of concern because children younger than 3 years of age are at high risk for hearing loss and language and learning disabilities. Clinicians should avoid prophylactic antibiotics against recurrent episodes, but they may offer tympanostomy tubes (T tubes).[4]

Adjunctive Therapy

Children with acute otitis media should be assessed and treated for pain. Those with pain should be recommended analgesics to reduce pain regardless of the decision to administer antibiotics.[4] This is largely because antibiotics do not reduce pain in the first 24 hours. Furthermore, some children may experience some pain up to 3 to 7 days even after antibiotics are started. Choice of pain treatment depends on possible benefits and risks to the individual patient. Acetaminophen and ibuprofen are mainstays of treatment, are effective analgesics for mild-to-moderate pain, and are readily available. Eardrops with a local anesthetic may offer additional, but brief, benefit over acetaminophen in patients at least 5 years of age.[4] Finally, several studies have documented the large risk reductions in pediatric pneumococcal acute otitis media.[12,13] Thus, routine assessment of vaccination schedules is essential for prevention.

Patient Care Process

Patient Care Process for Acute Otitis Media



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, weight)
- Patient history (eg, past infections, current and past antibiotic/antiviral use noting previous failures, medication allergies)
- Determine whether patient has concurrent purulent conjunctivitis
- Objective data:
    - Temperature
    - Signs and symptoms (see Clinical Presentation)
    - Presence of congestion, fullness, purulent discharge, or pain in the ear
    - Presence of redness, fullness, bulging, or limited/absent mobility of the tympanic membrane

Assess

- Infection status, including presence of signs and symptoms
- Determine which symptoms may need additional therapy (eg, ongoing ear pain)
- Use information collected, patient factors (eg, patient age, symptom severity, laterality), and joint decision-making with parents/caregivers to determine whether antibiotics are needed
- If antibiotics are appropriate, determine proper choice of antibiotic, dose, duration, and dosage form
    - Determine if the patient meets criteria for high-dose amoxicillin-clavulanate
    - Determine whether a short-course of therapy (5-7 days) may be appropriate

Plan

- Select drug therapy regimen including specific antibiotic, dose, route, frequency, and duration; specify the continuation and discontinuation of existing therapies (see Table 130-1)
- Monitor efficacy (eg, temperature, pain), safety (eg, medication-specific adverse effects), and time frame
- Educate patient and/or caregiver (eg, purpose of treatment, drug therapy) emphasizing adherence to treatment regimen

Implement[*]

- Provide patient education regarding the infection and all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up, when indicated
- Recommend measures to reduce ear pain, if present

Follow-up: Monitor and Evaluate

- Improvement/resolution of signs and symptoms; reassess the plan if the child’s symptoms worsen or decline within 48 to 72 hours of symptom onset
- Presence of adverse effects, particularly allergic reactions and diarrhea
- Patient adherence to treatment plan using multiple sources of information
- Recommend pneumococcal conjugate vaccine and annual influenza vaccination

[*] *Collaborate with patient, caregiver(s), and other healthcare professionals.*

Evaluation of Therapeutic Outcomes

Patients with acute otitis media should be reassessed after 48 to 72 hours. By this time, there should be clinical improvement in the signs and symptoms of infection, including pain, fever, and erythema/bulging of the tympanic membrane. If the patient has not responded and antibiotics were withheld initially, they should be instituted now.[14] If the patient initially received an antibiotic, then the antibiotic should be changed (Table 130-1). A switch in regimen is recommended if there is no clinical improvement by the third day of therapy, given the possibility of infection with a β-lactamase-producing strain of *H. influenzae* or *M. catarrhalis* or with a strain of penicillin-resistant *S. pneumoniae.* Most children will become asymptomatic within 7 days. Tympanocentesis for culture of middle ear fluid can be considered for treatment failure or persistent acute otitis media. It has a therapeutic effect of relieving pain and pressure and can be used to collect fluid to identify the causative agent.

Early reevaluation of the eardrum when signs and symptoms are improving can be misleading because effusions persist. Over a period of 1 week, changes in the eardrum normalize, and the pus becomes serous fluid. Air-fluid levels are apparent behind the eardrum, at which point the stage is now referred to as *otitis media with effusion*. This does not represent ongoing infection, nor are additional antibiotics required.[4]

Immediate reevaluation is appropriate if hearing loss results from persistent middle ear effusions following infection. Complications of otitis media are infrequent but include mastoiditis, bacteremia, meningitis, and auditory sequelae with the potential for speech and language impairment.[4]

ACUTE BACTERIAL RHINOSINUSITIS

Sinusitis is an inflammation and/or infection of the paranasal sinuses, or membrane-lined air spaces, around the nose.[15] The term *rhinosinusitis* is preferred because sinusitis typically also involves the nasal mucosa.[15] Even though the majority of rhinosinusitis infections are viral in origin, antibiotics are frequently prescribed. It is important to differentiate between viral and bacterial rhinosinusitis to avoid unnecessary antibiotic use.

The most current clinical practice guidelines for acute bacterial rhinosinusitis were published in 2012 by the Infectious Diseases Society of America (IDSA) and 2015 by the American Academy of Otolaryngology—Head and Neck Surgery Foundation (AAO-HNSF).[15,16]

Epidemiology

① Nearly 30 million cases of rhinosinusitis are diagnosed annually in the United States.[17] Adults with rhinosinusitis miss an average of 1 to 2 workdays/year with these infections and experience significant activity, work, and social limitations.[16] Most episodes of acute sinusitis are caused by viral upper respiratory tract infection; however, the lack of clinical criteria to accurately differentiate bacterial from viral infections leads to inappropriate use of antibiotics and remains the fifth leading diagnosis for which antibiotics are prescribed.[14,18]

Etiology

② Acute bacterial rhinosinusitis is caused, most often, by the same bacteria implicated in acute otitis media: *S. pneumoniae* and nontypeable *H. influenzae*. These organisms are responsible for approximately 50% to 70% of bacterial causes of acute bacterial rhinosinusitis in both adults and children.[15] *M. catarrhalis* is also sometimes implicated in children (approximately 8%-16%) and less commonly in adults.[15] *Streptococcus spp.*, *Staphylococcus aureus*, gram-negative bacilli, atypical bacteria, and anaerobes are associated less frequently with acute bacterial rhinosinusitis.[15] Healthcare-associated cases can be attributable to pathogens prevalent in the healthcare environment including *S. aureus*, methicillin-resistant *S. aureus* (MRSA), *P. aeruginosa*, *K. pneumoniae*, and other gram negatives; and often are polymicrobial.

Pathophysiology

Acute bacterial rhinosinusitis is often preceded by a viral respiratory tract infection that causes mucosal inflammation. This can lead to obstruction of the sinus ostia—the pathways that drain the sinuses. Mucosal secretions become trapped, local defenses are impaired, and bacteria from adjacent surfaces begin to proliferate. The maxillary and ethmoid sinuses are most frequently involved. The pathogenesis of chronic rhinosinusitis has not been well studied. Whether it is caused by more persistent pathogens or a subtle defect in the host's immune function, some patients develop chronic symptoms after their acute infection. Rarely, life-threatening complications of sinusitis can include meningitis, epidural, or cerebral abscess.

Clinical Presentation

CLINICAL PRESENTATION: ACUTE BACTERIAL RHINOSINUSITIS

General

The diagnosis of acute bacterial sinusitis involves assessing signs and symptoms, distinguishing bacterial from viral infection with temporal patterns of the illness. Patients manifest with focused sinonasal symptoms compared to those with viral UPIs. Acute sinusitis manifests with up to 4 weeks of purulent nasal drainage.

Signs and Symptoms

- Purulent anterior nasal discharge, purulent or discolored posterior nasal discharge, nasal congestion or obstruction, facial congestion or fullness, facial pain or pressure, fever, headache, ear pain/pressure/fullness, halitosis, dental pain, cough, and fatigue
- Clinical presentations (any of 3) that are most consistent with acute bacterial versus viral rhinosinusitis:

  i) Onset with *persistent* signs or symptoms compatible, lasting for ≥10 days without any evidence of clinical improvement

  ii) Onset with *severe* signs or symptoms of high fever (≥39°C [102.2°F]) and purulent nasal discharge or facial pain lasting for at least 3 to 4 consecutive days at the beginning of illness

  iii) Onset with *worsening* signs or symptoms characterized by new-onset fever, headache, or increase in nasal discharge following a typical viral URI that lasted 5 to 6 days and were initially improving ("double sickening")

Data from Reference 15.

Treatment

Desired Outcomes

The goals of treatment for acute bacterial rhinosinusitis are to reduce signs and symptoms, achieve and maintain patency of the ostia, limit antibiotic treatment to those who may benefit, eradicate the bacterial infection with appropriate antibiotic therapy, minimize the duration of illness, prevent complications, and prevent progression from acute disease to chronic disease.

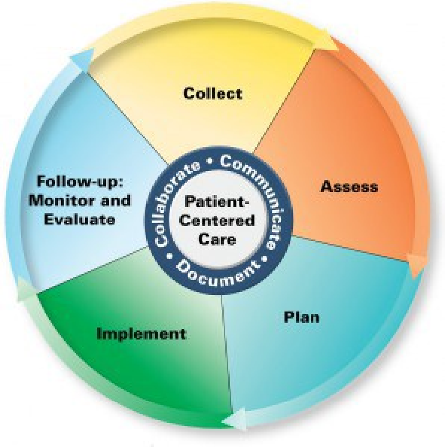
General Approach to Treatment

④ The first step is to differentiate viral and bacterial rhinosinusitis. This is based on disease duration, initial severity of illness, and worsening symptomatology. Viral rhinosinusitis typically improves in 7 to 10 days. In contrast, acute bacterial rhinosinusitis symptoms persist for 10 days or greater without improvement or with worsening symptoms after 10 days, or can manifest worsening after initial improvement ("double-sickness" pattern).[16] Acute bacterial rhinosinusitis may also be suspected if the patient has severe symptoms at the beginning of his/her illness. Management involves antibiotic therapy or watchful waiting based on shared decision making. Amoxicillin-clavulanate is the first-line antibiotic therapy for patients with acute bacterial rhinosinusitis.[15]

Indications for urgent early referral to a specialist is essential for patients exhibiting complicated acute bacterial rhinosinusitis including high, persistent fevers, periorbital edema or inflammation, mental status changes, visual disturbances, severe headache, immunosuppressive illness, healthcare-associated infections, anatomic defects causing obstruction, unusually severe symptoms, multiple recurrent episodes (three to four times per year), unilateral findings, significant coexisting illnesses, risk factors for unusual or resistant pathogens, and history of antibiotic failure. The specialist may perform computed tomography to assess the severity and extent of disease and identify the underlying causes.

Patient Care Process

Patient Care Process for Acute Bacterial Rhinosinusitis



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, weight, comorbidities)
- Patient history (eg, past infections, current and past antibiotic/antiviral use noting previous failures, medication allergies, history of allergic rhinitis)
- Recent healthcare exposures or procedures
- Temporal patterns of symptoms
- Determine whether patient is in daycare, is a daycare worker, or has a child in daycare
- Objective data:
    - Temperature

- Signs and symptoms (see Clinical Presentation)
- Presence of congestion, fullness, or pain in the nose, face, or ear
- Presence of purulent or discolored nasal discharge
- Other diagnostic tests, when indicated (eg, CT, sinus puncture)

Assess

- Infection status, including presence and severity of signs and symptoms
- Determine which symptoms may need additional therapy (eg, ongoing nose pain)
- Decide if referral is needed (eg, mental status changes, visual disturbances, immunosuppressive illness, nosocomial infections, anatomic defects, unilateral findings)
- Use information collected, patient factors (eg, patient age, symptom severity), and joint decision making with parents/caregivers to determine whether antibiotics are needed
- If antibiotics are appropriate, determine proper choice of antibiotic, dose, duration, and dosage form
    - Determine if the patient meets criteria for high-dose amoxicillin-clavulanate

Plan[*]

- Select drug therapy regimen including specific antibiotic, dose, route, frequency, and duration; specify the continuation and discontinuation of existing therapies (see Tables 126-2 and 126-3)
- Monitor efficacy (eg, temperature, pain), safety (eg, medication-specific adverse effects), and time frame
- Educate patient and/or caregiver (eg, purpose of treatment, drug therapy) emphasizing adherence to treatment regimen

Implement

- Provide patient education regarding the infection and all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up, when indicated
- Recommend symptomatic measures to reduce nose pain and inflammation

Follow-up: Monitor and Evaluate

- Improvement/resolution of signs and symptoms; reassess the plan if the patient’s symptoms worsen or decline within 48 to 72 hours of symptom onset
- Presence of adverse effects, particularly allergic reactions and diarrhea
- Patient adherence to treatment plan using multiple sources of information

[*] *Collaborate with patient, caregiver(s), and other healthcare professionals.*

Pharmacologic Therapy

The IDSA published clinical practice guidelines in 2012 that are the primary source for many of the statements in this chapter.[15] Additional guidance and recommendations come from a 2015 update of the 2007 guidelines from AAO-HNSF.[16] There are two major differences in the IDSA and AAO-HNSF guidelines. The AAO-HNSF guidelines endorse watchful waiting, without antibiotics, unless symptoms fail to improve within 7 days.[16] When antibiotics are given, the AAO-HNSF endorses amoxicillin as first-line treatment, instead of amoxicillin-clavulanate.[16] In contrast, the IDSA guidelines support initiating empiric therapy as soon as the clinical diagnosis of acute bacterial rhinosinusitis is established and amoxicillin-clavulanate rather than amoxicillin alone as first-line treatment.[15]

⑤ Amoxicillin-clavulanate is considered the first-line treatment for acute bacterial rhinosinusitis in children and adults according to IDSA guidelines (Tables 130-2 and 130-3).[15] In contrast, prior guidelines, and the AAO-HNSF guidelines,[16] list amoxicillin as the first-line treatment option due to its safety, narrow spectrum of activity, good tolerability, and favorable cost. The IDSA guidelines support the choice of amoxicillin-clavulanate based on (a) the emergence of *H. influenzae* as a more common cause of upper respiratory tract infections in children than in the past,[5] and (b) the high prevalence of β-lactam-producing respiratory pathogens in acute bacterial rhinosinusitis (particularly *H. influenzae* and *M. catarrhalis*). The advantage of using amoxicillin-clavulanate, as compared with amoxicillin, is a greater spectrum of coverage. The disadvantages are increased cost, greater risk of adverse effects including diarrhea, and an added risk of hypersensitivity to the clavulanate component.[15]

TABLE 130-2

Antibiotics and Doses for Acute Bacterial Rhinosinusitis in Children

Antibiotic	Brand Name	Dose	Comments
Initial Empirical Therapy			
Amoxicillin-clavulanate	Augmentin®	45 mg/kg/day orally twice daily	First line
Amoxicillin-clavulanate	Augmentin®	90 mg/kg/day orally twice daily	Second line
β-Lactam Allergy			
Clindamycin plus cefixime or cefpodoxime	Cleocin®, Suprax®, Vantin®	Clindamycin (30-40 mg/kg/day orally three times daily) cefixime (8 mg/kg/day orally twice daily) or efpodoxime (10 mg/kg/day orally twice daily)	Non-type 1 allergy
Levofloxacin	Levaquin®	10-20 mg/kg/day orally every 12-24 hours	Type 1 allergy
Risk for Antibiotic Resistance or Failed Initial Therapy			
Amoxicillin-clavulanate	Augmentin®	90 mg/kg/day orally twice daily	
Clindamycin plus cefixime or cefpodoxime	Cleocin®, Suprax®, Vantin®	Clindamycin (30-40 mg/kg/day orally three times daily) plus Cefixime (8 mg/kg/day orally twice daily) or Cefpodoxime (10 mg/kg/day orally twice daily)	
Levofloxacin	Levaquin®	10-20 mg/kg/day orally every 12-24 hours	
Severe Infection Requiring Hospitalization			
Ampicillin-sulbactam	Unasyn®	200-400 mg/kg/day IV every 6 hours	
Ceftriaxone	Rocephin®	50 mg/kg/day IV every 12 hours	
Cefotaxime	Claforan®	100-200 mg/kg/day IV every 6 hours	
Levofloxacin	Levaquin®	10-20 mg/kg/day IV every 12-24 hours	

Data from Reference 15.

TABLE 130-3

Antibiotics and Doses for Acute Bacterial Rhinosinusitis in Adults

Antibiotic	Brand Name	Dose	Comments
Initial Empirical Therapy			
Amoxicillin-clavulanate	Augmentin®	500 mg/125 mg orally three times daily, or 875 mg/125 mg orally twice daily	First-line
Amoxicillin-clavulanate	Augmentin®	2,000 mg/125 mg orally twice daily	Second- line
Doxycycline		100 mg orally twice daily or 200 mg orally once daily	Second- line
β-Lactam Allergy			
Doxycycline		100 mg orally twice daily or 200 mg orally once daily	
Levofloxacin	Levaquin®	500 mg orally once daily	
Moxifloxacin	Avelox®	400 mg orally once daily	
Risk for Antibiotic Resistance or Failed Initial Therapy			
Amoxicillin-clavulanate	Augmentin®	2,000 mg/125 mg orally twice daily	
Levofloxacin	Levaquin®	500 mg orally once daily	
Moxifloxacin	Avelox®	400 mg orally once daily	
Severe Infection Requiring Hospitalization			
Ampicillin-sulbactam	Unasyn®	1.5-3 g IV every 6 hours	
Levofloxacin	Levaquin®	500 mg orally once daily	
Moxifloxacin	Avelox®	400 mg orally once daily	
Ceftriaxone	Rocephin®	1-2 g IV every 12-24 hours	
Cefotaxime	Claforan®	2 g IV every 4-6 hours	

Data from Reference 15.

Symptomatic Management

Symptomatic management for acute rhinosinusitis aims to relieve symptoms due to nasal drainage and obstruction such as pain with use of analgesics. The following are recommended as adjunct to therapy in patients with acute bacterial rhinosinusitis[15]:

- Intranasal saline irrigation with either physiologic or hypertonic saline
- Intranasal corticosteroids as adjunct to antibiotics in the empiric treatment of acute bacterial rhinosinusitis, primarily in patients with a history of allergic rhinitis

Topical or oral decongestants or antihistamines are generally not recommended as adjunctive treatment for acute bacterial rhinosinusitis. These agents can dry mucosa and disturb clearance of mucosal secretions.

High-dose amoxicillin-clavulanate (eg, 2,000 mg twice daily or 90 mg/kg/day twice daily) is recommended in the following situations: (a) geographic regions with high endemic rates (10% or greater) of invasive penicillin-nonsusceptible *S. pneumoniae*, (b) severe infection, (c) attendance at daycare, (d) age less than 2 or greater than 65 years, (e) recent hospitalization, (f) antibiotic use within the last month, and (g) immunocompromised persons.[15] Severe infections are those with “evidence of systemic toxicity with fever of 39°C (102.2°F) or higher, and threat of suppurative complications.”[15]

For those with a history of β-lactam allergy, levofloxacin monotherapy is recommended for children or combination therapy with clindamycin plus cefixime or cefpodoxime.[15] Adults with a penicillin allergy may receive doxycycline (not suitable for children), levofloxacin, or moxifloxacin monotherapy.[15] The ISDA guidelines also provide several options for patients at risk for antibiotic resistance, who failed initial therapy, or who have a severe infection requiring hospitalization (Tables 130-2 and 130-3).[15] Notably, cephalosporins are no longer recommended as monotherapy due to variable rates of resistance against *S. pneumoniae*.[15] Combination therapy with a third-generation oral cephalosporin plus clindamycin may be used in regions with high endemic rates of penicillin nonsusceptible *S. pneumoniae*. Macrolides are not recommended because of high rates of *S. pneumoniae* resistance (~30%).[15] Trimethoprim-sulfamethoxazole has not been recommended for some time due to resistance among *S. pneumoniae* and *H. influenzae* (~30-40%).[15]

The duration of therapy for the treatment of uncomplicated acute bacterial rhinosinusitis is 5 to 7 days for most adults. A longer duration of 10 to 14 days is still recommended for children.[15]

Evaluation of Therapeutic Outcomes

If symptoms persist or worsen after 48 to 72 hours of appropriate antibiotic therapy, then the patient should be reevaluated and alternative antibiotics should be considered.[15] Patients who do not respond to first- or second-line therapies should be referred to a specialist and evaluated more aggressively, potentially with direct sinus aspiration or contrast-enhanced computed tomography.[15]

ACUTE PHARYNGITIS

① ② Pharyngitis is an acute infection of the oropharynx or nasopharynx.[19] The most common presenting symptom is sore throat. It is responsible for 6% of visits by children to their primary care provider annually.[20] Although viral causes are most common, group A β-hemolytic *Streptococcus* (GAS, also known as *S. pyogenes*) is the primary bacterial cause[19]; pharyngitis due to GAS is commonly known as “strep throat,” accounting for 20% to 30% of cases among children and 5% to 15% among adults.

Epidemiology

Acute pharyngitis accounts for approximately 15 million healthcare visits per year, resulting in an economic burden of up to $539 million for children alone.[19]

Although all age groups are susceptible, the frequency is much greater in the pediatric population. Children 5 to 15 years of age are most susceptible; parents of school-aged children and those who work with children are also at increased risk.

Seasonal outbreaks occur, and the incidence of GAS is highest in winter and early spring.[19] The incubation period is 2 to 5 days, and the illness often occurs in clusters.[19] Spread occurs via direct contact (usually from hands) with droplets of saliva or nasal secretions, and transmission is thus worse in institutions, schools, families, and crowded areas.[19] Untreated, patients with streptococcal pharyngitis are infectious during the acute illness and for another week thereafter. Effective antibiotic therapy reduces the infectious period to about 24 hours.

Acute rheumatic fever is rarely seen in developed countries. In the United States, acute rheumatic fever secondary to GAS infection was a cause of concern in the 1950s and was the major reason for penicillin therapy, but the annual incidence of this disease today is extremely rare (one case or more per 1 million population). Outbreaks have been reported in the United States as recently as the late 1980s and early 1990s. In developing countries, acute rheumatic fever and rheumatic heart disease is widespread affecting an estimated 20 million people worldwide making this a leading cause of cardiac death during the first five decades of life. This risk can be reduced by timely therapy.

Etiology

① Viruses cause the majority of acute pharyngitis cases. Specific etiologies include rhinovirus (20%), coronavirus (5%), adenovirus (5%), herpes simplex virus (4%), influenza virus (2%), parainfluenza virus (2%), and Epstein–Barr virus (1%) and less frequently coxsackievirus A, cytomegalovirus, and acute HIV infection.[19]

④ GAS is the most common cause of pharyngitis (10%-30% of persons of all ages with pharyngitis) and is the only commonly occurring form of acute pharyngitis for which antibiotic therapy is indicated.[19] In the pediatric population, GAS causes 15% to 30% of pharyngitis cases. In adults, GAS is responsible for 5% to 15% of all symptomatic episodes of pharyngitis.[19] Pharyngitis in a child younger than 3 years of age is rarely caused by GAS.[19]

Other less common causes of acute pharyngitis are groups C and G *Streptococcus*, *Corynebacterium diphtheriae*, *Neisseria gonorrhoeae*, *Mycoplasma pneumoniae*, *Arcanobacterium haemolyticum*, *Yersinia enterocolitica*, and *Chlamydia pneumoniae*.[19] Treatment options for these organisms are not addressed in this chapter.

Pathophysiology

Streptococcal pharyngitis results from GAS proliferating in the pharynx, although exact mechanisms are not well defined. Asymptomatic pharyngeal carriers of the organism may have an alteration in host immunity (eg, a breach in the pharyngeal mucosa) and the bacteria of the oropharynx may migrate to cause an infection. Pathogenic factors associated with the organism itself, pyrogenic toxins, hemolysins, streptokinase, and proteinase, may also play a role.

Clinical Presentation

CLINICAL PRESENTATION: GROUP A STREPTOCOCCAL PHARYNGITIS

General

- A sore throat of sudden onset that is mostly self-limited.
- Fever and constitutional symptoms resolving in about 3 to 5 days.
- Clinical signs and symptoms are similar for viral causes and nonstreptococcal bacterial causes.

Signs and Symptoms of GAS Pharyngitis

- Sore throat
- Pain on swallowing
- Fever
- Headache, nausea, vomiting, and abdominal pain (especially in children)
- Erythema/inflammation of the tonsils and pharynx with or without patchy exudates
- Enlarged, tender lymph nodes
- Red swollen uvula, petechiae or purple spots on the soft palate, and a scarlatiniform rash

Signs Suggestive of Viral Origin for Pharyngitis

- Conjunctivitis
- Coryza
- Cough

Laboratory Tests

- Throat swab and culture
- Rapid antigen-detection test (RADT)

Data from Reference 19.

The primary goal of diagnosis is accurate differentiation of GAS from pharyngitis due to other agents (eg, viral). There is broad overlap between the signs and symptoms of pharyngitis from GAS versus viral or nonstreptococcal agents, and thus rarely can be differentiated based on clinical grounds alone even among the most experienced clinicians.

Guidelines from IDSA and the American Heart Association recommend swabbing the throat and testing for GAS in patients with signs and symptoms of streptococcal pharyngitis.[19] Only those with a positive test for GAS require antibiotic treatment.[19] Diagnostic studies are not indicated for children <3 years old because the incidence of streptococcal pharyngitis is uncommon in this age. Laboratory tests should not be performed in patients with clinical features that strongly suggest a viral etiology. This is because a positive test does not necessarily indicate disease. A positive test may simply indicate that the patient is a carrier for GAS and is not actively infected. Approximately 20% of children are carriers of GAS; the prevalence is lower among adults.[19]

Testing for GAS can be performed using a throat swab that can be sent for culture or used for the RADT. Cultures are the gold standard, but they require 24 to 48 hours for results. The RADT is more practical in that it provides results quickly, it can be performed at the bedside, and it is less expensive than culture. If RADT is positive, it does not require a follow-up throat culture.[19] If RADT yields negative test results, it is generally recommended to follow up with a throat culture to confirm the results for children and adolescents, but not necessary in adults.[19] Delaying therapy while awaiting culture results does not affect the risk of complications (though some argue that symptomatic benefit is postponed, and contagion remains), and patients must be educated as to the value of waiting, given the low false-negative rate of RADT.[19] The accurate diagnosis of streptococcal pharyngitis followed by appropriate antimicrobial therapy is important for the prevention of suppurative and nonsuppurative complications including acute rheumatic fever, acute glomerulonephritis, reactive arthritis, peritonsillar abscess, retropharyngeal abscess, cervical lymphadenitis, mastoiditis, otitis media, rhinosinusitis, and necrotizing fasciitis. In addition, accurate diagnosis would allow to improve outcomes, decrease transmission, and minimizing potential inappropriate antimicrobial therapy.

Treatment

Desired Outcomes

The goals of treatment for pharyngitis are to improve clinical signs and symptoms, minimize adverse drug reactions and overuse of antibiotics, prevent transmission to close contacts, and prevent acute rheumatic fever and suppurative complications, such as peritonsillar abscess, cervical lymphadenitis, and mastoiditis.[19]

General Approach to Treatment

Once the diagnosis of GAS pharyngitis has been made, the clinician must decide appropriate supportive care, when to initiate antibiotic therapy, the appropriate antibiotic, and the duration of therapy. The selection of appropriate antibiotic therapy will involve careful consideration of cost, safety, efficacy, potential for regimen adherence, and bacterial resistance rates. Clinicians should be aware of local resistance patterns, which may differ from the national patterns.

④ Inappropriate antibiotic use for acute pharyngitis has been a major contributor to the development antimicrobial resistance.[19] Approximately 60% of patients who visit their provider with a complaint of “sore throat are prescribed an antibiotic.”[21, 22] This rate is well above the incidence of GAS pharyngitis. Antibiotic therapy should be reserved for those patients with clinical and epidemiologic features of GAS pharyngitis, preferably with a positive laboratory test. Empirical therapy is not recommended; however, if used while results are pending, it is important to discontinue empirical antibiotics once laboratory results come back as negative.

Pharmacologic Therapy

The clinical practice guidelines published by the IDSA in 2012 are the primary source for many of the recommendations in this section.[19] Tables 130-4 and 130-5 outline dosing for acute GAS pharyngitis and chronic carriers of GAS.

TABLE 130-4

Antibiotics and Doses for Group A β-Hemolytic Streptococcal Pharyngitis

Antibiotic	Brand Name	Dose	Route / Duration	Rating
Preferred Antibiotics				
Penicillin V	Pen-V®	Children: 250 mg twice daily or three times daily orally. Adolescents and Adults: 250 mg four times daily or 500 mg twice daily	Orally 10 days	IB
Penicillin G benzathine	Bicillin L-A®	<27 kg: 0.6 million units; ≥ 27 kg : 1.2 million units	IM One dose	IB
Amoxicillin[a]	Amoxil®	50 mg/kg once daily (maximum 1 g); 25 mg/kg (maximum 500 mg) twice daily	Orally 10 days	IB
Penicillin Allergy				
Cephalexin	Keflex®	20 mg/kg/dose (maximum 500 mg)	Orally 10 days	IB
Cefadroxil	Duricef®	30 mg/kg once daily (maximum 1 g)	Orally 10 days	IB
Clindamycin	Cleocin®	7 mg/kg/dose three times daily (maximum 300 mg/dose)	Orally 10 days	IIaB
Azithromycin[b]	Zithromax®	12 mg/kg once daily (maximum 500 mg) for one day, then 6 mg/kg orally once daily (maximum 250 mg) for four days	Orallly 5 days	IIaB
Clarithromycin[b]	Biaxin®	7.5 mg/kg per (maximum 250 mg) twice daily	Orally 10 days	IIaB

These guidelines provide a systematic weighting of the strength of the recommendation (Class I, conditions for which there is evidence and/or general agreement that a given procedure or treatment is beneficial, useful, and effective; Class II, conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a procedure or treatment; Class IIa, weight of evidence/opinion is in favor of usefulness/efficacy; Class IIb, usefulness/efficacy is less well established by evidence/opinion; Class III, conditions for which there is evidence and/or general agreement that a procedure/treatment is not useful/effective and in some cases may be harmful) and quality of evidence (A, data derived from multiple randomized clinical trials or meta-analyses; B, data derived from a single-randomized trial or nonrandomized studies; C, only consensus opinion of experts, case studies, or standard of care).

[a] Standard formulation, not extended release.

[b] Resistance of group A β-hemolytic *Streptococcus* (GAS) to these agents may vary and local susceptibilities should be considered with these agents.

Data from Reference 19.

TABLE 130-5

Antibiotics and Doses for Eradication of Group A β-Hemolytic Streptococcal Pharyngitis in Chronic Carriers

Antibiotic	Brand Name	Dose
Clindamycin	Cleocin®	20-30 mg/kg/day orally in three divided doses (maximum 300 mg/dose) for 10 days
Amoxicillin-clavulanate	Augmentin®	40 mg/kg/day orally in three divided doses (maximum 2,000 mg/day of amoxicillin) for 10 days
Penicillin V and rifampin	Pen-V®, Rifadin®	Penicillin V: 50 mg/kg/day orally in four divided doses for 10 days (maximum 2,000 mg/day); Rifampin: 20 mg/kg/day orally in one dose for the last 4 days of treatment (maximum 600 mg/day)
Penicillin G benzathine and rifampin	Bicillin L-A®, Rifadin®	Penicillin G benzathine: <27 kg—0.6 million units once IM, ≥ 27 kg 1.2 million units once intramuscularly; *and* Rifampin: 20 mg/kg/day orally in two divided doses during last 4 days of treatment with penicillin (maximum 600 mg/day)

Data from Reference 19.

⑤ In the United States there have been no reported cases of penicillin-resistant GAS.[19] Because penicillin and amoxicillin have a narrow spectrum of activity and are readily available, safe, and inexpensive, they are considered to be the treatments of choice.[19]

Amoxicillin often used in place of penicillin V for children with GAS pharyngitis because the suspension is more palatable.[19] Gastrointestinal (GI) adverse effects and rash are more common with amoxicillin. A once-daily, extended-release formulation of amoxicillin has been approved for treatment of GAS pharyngitis in adults and children aged 12 years and older.[19] In addition, a number of antibiotics have been effective against GAS pharyngitis (Table 130-4). Most oral regimens are administered for 10 days.

In patients with nonanaphylactic penicillin allergy, a first-generation cephalosporin such as cephalexin is recommended for 10 days. For patients with type I immunoglobulin E (IgE)–mediated penicillin allergies, azithromycin, clarithromycin, or clindamycin is recommended for a duration of 10 days except 5 days with azithromycin. Clindamycin resistance among GAS is ~1% and 5% to 8% for macrolides in the United States, but is higher in some other areas of the world.[19]

A few antimicrobials are not recommended for GAS pharyngitis including tetracyclines due to high prevalence of resistance as well as sulfonamides and trimethoprim-sulfamethoxazole due to poor eradication rates for GAS.[19] Older fluoroquinolones such as ciprofloxacin have poor activity against GAS while newer fluoroquinolones have activity against GAS, but are expensive and have an unnecessarily broad spectrum of activity for this treatment for GAS pharyngitis.[19] Treatment early in the course leads to more rapid clinical response in symptoms, decreases contagiousness to others, and can prevent suppurative and nonsuppurative complications. The immediate therapy can be postponed up to 9 days without major nonsuppurative sequela.[19] Clinical guidelines recommend withholding antibiotics unless the patient has a positive laboratory result.[19]

The severity of pharyngitis symptoms and communicability of the disease is less after 24 hours of antibiotic therapy. The duration of therapy for GAS pharyngitis is 10 days, except for benzathine penicillin and azithromycin, to maximize bacterial eradication.[19] A systematic review of short- versus long-course therapies concluded that oral penicillin for 10 days (long course) remains first-line therapy.[23] Although some studies have suggested shorter courses of treatment for pharyngitis, confounding factors from these studies, such as the lack of strict entry criteria or differentiation between new and failed infections, limit the widespread application of short-antibiotic courses now.[19]

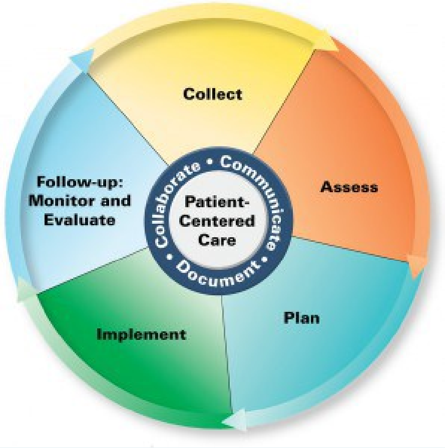
Approximately 33% of household contacts of a person with acute GAS pharyngitis harbor GAS in their upper respiratory tracts.[19] Routine testing and/or treating of asymptomatic household contacts of an index patient is not recommended.[19] GAS carriers do not need antimicrobial therapy due to low risk of spreading GAS pharyngitis or developing suppurative or nonsuppurative complications.[18] If tested, it is not necessary to treat asymptomatic carriers. It is difficult to ascertain the cause of symptomatic pharyngitis in carriers of GAS if they do develop symptoms. Clinicians need to differentiate whether the patient is experiencing a repeat GAS infection or a chronic carrier of GAS because laboratory tests will be positive in these patients.[19]

When acute GAS pharyngitis occurs in a carrier, a treatment course of appropriate antibiotics is recommended.[19] Table 130-5 outlines antimicrobials for the eradication of GAS in chronic carriers experiencing symptomatic episodes. In the treatment of recurring episodes of culture-positive GAS pharyngitis, there are several alternative antibiotics which are preferred over penicillin or amoxicillin with GAS carriers. Amoxicillin-clavulanate, clindamycin, penicillin/rifampin combination, and benzathine penicillin G/rifampin combination may be considered for recurrent episodes of pharyngitis to maximize bacterial eradication in potential carriers and to counter copathogens that produce β-lactamases.[19]

Factors that should be considered when personalizing therapy for a patient include allergy status, prior antibiotic use, and adherence. Those with a history of antibiotic use for acne may be at higher risk for resistant strains of GAS. Short-course antibiotics or penicillin G benzathine may be considered in patients with a history of nonadherence. Supportive care should be offered to all patients with acute pharyngitis including antipyretic medications, analgesics, and nonprescription lozenges and sprays containing menthol and topical anesthetics for temporary relief of pain.[19] There are limited data for use of corticosteroids to reduce the symptoms of GAS pharyngitis, and given the risk of adverse effects, their use is not recommended.[19] Because pain is often the primary reason for visiting a physician, emphasis on analgesics such as acetaminophen and nonsteroidal anti-inflammatory drugs to aid in pain relief is strongly recommended.

Patient Care Process

Patient Care Process for Acute Pharyngitis



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document

Collect

- Patient characteristics (eg, age, weight)
- Patient history (eg, past infections including rheumatic fever and rheumatic heart disease, current and past antibiotic/antiviral use noting previous failures, medication allergies)
- Determine whether patient is a school-age child, parent/caregiver of a school-age child, or works with school-age children
- Objective data:
  - Temperature
  - Signs and symptoms (see Clinical Presentation)
  - Other diagnostic tests, when indicated (eg, RADT, throat culture, microbiologic testing)

Assess

- Infection status, including presence of signs and symptoms
- Determine which symptoms may need additional therapy (eg, ongoing throat pain)
- Use information collected, patient factors (eg, patient age, symptom severity), and joint decision making with parents/caregivers to determine whether antibiotics are needed
- If antibiotics are appropriate, determine proper choice of antibiotic, dose, duration, and dosage form

Plan*

- Select drug therapy regimen including specific antibiotic, dose, route, frequency, and duration; specify the continuation and discontinuation of existing therapies (see Tables 130-4 and 130-5)
- Monitor efficacy (eg, temperature, pain), safety (eg, medication-specific adverse effects), and time frame
- Educate patient and/or caregiver (eg, purpose of treatment, drug therapy) emphasizing adherence to treatment regimen
- Recommend self-monitoring of body temperature

Implement*

- Provide patient education regarding the infection and all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up, when indicated
- Recommend measures to reduce throat pain, if present

Follow-up: Monitor and Evaluate

- Presence of adverse effects, particularly allergic reactions
- Patient adherence to treatment plan using multiple sources of information
- Inquire if there have been infections among household contacts

******Collaborate with patient, caregiver(s), and other healthcare professionals.*

Evaluation of Therapeutic Outcomes

Most pharyngitis cases are self-limited; however, antibiotics hasten resolution when given early for proven cases of GAS pharyngitis.[19] Generally, fever and other symptoms resolve within 3 to 4 days of onset without antibiotics; however, symptoms will improve 0.5 to 2.5 days earlier with antibiotic therapy.[19] Follow-up testing is generally not necessary for index cases or asymptomatic contacts[19]; however, throat cultures 2 to 7 days after completion of antibiotics are warranted for patients who remain symptomatic or when symptoms recur despite completion of treatment.[19]

SELF-ASSESSMENT QUESTIONS

1. Which of the following are recommended before taking an *initial observation* approach in a patient with acute otitis media?

A. Temperature less than 39°C (102.2°F).

B. Joint decision-making with patients and caregivers.

C. Action plan to administer antibiotics if symptoms worsen within 48 to 72 hours.

D. All of the above must be in place before recommending initial observation.

2. Which of the following characteristics can help differentiate between acute otitis media and otitis media with effusion?

A. Middle ear effusion.

B. Cough.

C. Ear pain.

D. Two of the above are correct.

3. Which of the following is considered to be a first-line recommendation for the treatment of a 1-year-old child with acute otitis media and a fever of 103°F (39.4 °C)?

A. Azithromycin

B. Amoxicillin

C. Ceftriaxone

D. Cefuroxime

4. A child with moderate symptoms of acute otitis media returns to clinic after taking amoxicillin for 4 days without improvement, which of these alternatives would you recommend?

A. Amoxicillin-clavulanate

B. Trimethoprim-sulfamethoxazole

C. Ceftriaxone

D. Erythromycin-sulfisoxazole

5. Which of the following vaccines can help prevent episodes of acute otitis media?

A. Pneumococcal conjugate vaccine.

B. Seasonal influenza vaccine.

C. Tetanus, diphtheria, and pertussis vaccine.

D. Two of the above are correct.

6. Which of the following patients should receive amoxicillin-clavulanate instead of amoxicillin for acute otitis media?

A. Patient who received amoxicillin for another infection 2 weeks prior to this visit.

B. Patient with purulent conjunctivitis and acute otitis media.

C. Both of these patients should receive amoxicillin-clavulanate instead of amoxicillin.

D. Neither of these patients should receive amoxicillin-clavulanate instead of amoxicillin.

7. Which of the following is the most common pathogen in acute rhinosinusitis?

A. Viruses

B. Streptococcus pneumoniae

C. Haemophilus influenzae

D. Moraxella catarrhalis

8. Which of the following is suggestive of bacterial versus viral rhinosinusitis?

A. Persistent symptoms for 10 days or more.

B. Worsening of symptoms after 7 days.

C. Lack of symptomatic response to nonprescription nasal decongestants.

D. Two or more of the above are correct.

9. Which of the following is considered to be a first-line recommendation for the treatment of a 68-year-old man with a 2-week history of persistent nasal congestion and sinus pain? The man received 10 days of clindamycin when he was hospitalized for a skin abscess 2 months ago.

A. Amoxicillin-clavulanate

B. Clarithromycin

C. Levofloxacin

D. Amoxicillin

10. Which of the following nonprescription medications is recommended for the management of patients with acute bacterial rhinosinusitis?

A. Nasal antihistamine.

B. Oral antihistamine.

C. Nasal decongestant.

D. None of the above are recommended for a patient with acute bacterial rhinosinusitis.

11. A 10-year-old male presents to the pediatrician's office with severe throat pain and dysphagia. His highest temperature was 99.9°F (37.7°C). During the physical exam, he is found to have swollen tonsils but no swelling of the anterior cervical nodes. Based on the above information, when is antibiotic therapy recommended?

A. Clinical criteria present

B. Clinical criteria present and RADT test positive

C. Clinical criteria present and laboratory results pending

D. B and C

12. Which of the following is NOT consistent with the clinical presentation of GABHS pharyngitis.

A. Enlarged, tender lymph nodes

B. Sore throat

C. No cough

D. Conjunctivitis

13. A local daycare reports several cases of GABHS pharyngitis. How many days must pass before the risk of additional cases is no longer a concern?

A. 1 day

B. 5 days

C. 10 days

D. 14 days

14. The most appropriate therapy for a young adult (weighing 70 kg) diagnosed with GABHS pharyngitis and has a penicillin allergy (anaphylaxis) is:

A. Tetracycline 500 mg PO BID for 10 days

B. Levofloxacin 750 mg PO daily for 10 days

C. Penicillin V 500 mg PO twice daily for 10 days

D. Azithromycin 500 mg PO once daily for one day, then 250 mg once daily for 4 days

15. A 9-year-old female (weighing 30 kg) is diagnosed with pharyngitis. Which of the following is most appropriate?

A. Amoxicillin suspension 400 mg / 5 mL: Take 12.5 mL PO once daily for 10 days

B. Clindamycin hydrochloride 75 mg capsules: Take three capsules PO thrice daily for 10 days

C. Sulfamethoxazole-trimethoprim 200 mg / 40 mg per 5 mL oral suspension: Take three teaspoonfuls PO twice daily for 5 days

D. Penicillin benzathine 0.6 million units IM: Administer one dose

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** Initial observation approach for acute otitis media should all be based on join decision making with patients/caregivers, have a plan to initiate antibiotics if symptoms worsen or decline within 48 to 72 hours of symptom onset, and can be considered for:
   - Children 6 months and older with nonsevere unilateral acute otitis media without otorrhea
   - Children 24 months and older with bilateral acute otitis media without otorrhea
   - Patients with temperatures of less than 39°C (102.2°F)
2. **C.** Otitis media with effusion is characterized by fluid in the middle ear without signs and symptoms of acute ear infection, such as pain and a bulging eardrum.
3. **B.** High-dose amoxicillin (80-90 mg/kg/day in two divided doses) is recommended for most pediatric patients with acute otitis media.
4. **A.** Clinicians should reassess all plans if the child's symptoms worsen or decline within 48 to 72 hours. First-line treatment for treatment failure at

48-72 hours is amoxicillin-clavulanate.

5. **D.** The pneumococcal conjugate vaccine and annual influenza vaccination have shown to decrease risk of acute otitis media.
6. **C.** Children who have received amoxicillin in the last 30 days, have concurrent purulent conjunctivitis, or have a history of recurrent infection unresponsive to amoxicillin should receive amoxicillin-clavulanate instead due to likely resistant infection with the presence of a β-lactamase.
7. **A.** Majority of acute rhinosinusitis infectious are viral in origin.
8. **D.** Viral rhinosinusitis typically improves in 7 to 10 days. In contrast, acute bacterial rhinosinusitis symptoms persist for 10 days or greater without improvement or with worsening symptoms after 10 days or can manifest worsening after initial improvement (“double-sickness” pattern). Acute bacterial rhinosinusitis may also be suspected if the patient has severe symptoms at the beginning of his/her illness.
9. **A.** Amoxicillin-clavulanate is considered the first-line treatment for acute bacterial rhinosinusitis in children and adults according to IDSA guidelines. The patient is also likely to be experiencing a resistant bacterial rhinosinusitis infection due to recent antibiotic treatment and hospitalization with a 2-week history of persistent symptoms.
10. **D.** Topical or oral decongestants or antihistamines are generally not recommended as adjunctive treatment for acute bacterial rhinosinusitis. These agents can dry mucosa and disturb clearance of mucosal secretions.
11. **B.** Patient presents symptoms meeting clinical criteria for acute pharyngitis per severe throat pain, dysphagia, fever, and swollen tonsils. Antibiotic therapy is recommended only for those with a positive test for GAS usually confirmed by a RADT.
12. **D.** GAS pharyngitis symptoms:
    - Soar throat
    - Pain on swallowing
    - Fever
    - Headache, nausea, vomiting, and abdominal pain (especially in children)
    - Erythema/inflammation of the tonsils and pharynx with or without patchy exudates
    - Enlarged, tender lymph nodes
    - Red swollen uvula, petechiae or purple spots on the soft palate and scarlatiniform rash

    Signs of viral origin pharyngitis
    - Conjunctivitis
    - Coryza
    - Cough
13. **B.** The incubation period of GAS pharyngitis ranges from 2 to 5 days; therefore, the risk of additional cases is no longer a concern after 5 days.
14. **D.** Due to prevalence of resistance, tetracyclines, sulfonamides, and trimethoprim-sulfamethoxazole are not recommended for GAS pharyngitis. Newer fluoroquinolones have activity against GAS but are expensive and have an unnecessarily broad spectrum of activity. Azithromycin is an appropriate treatment for patients with penicillin allergy; however, local susceptibilities should be considered before recommending this medication.
15. **A.** Penicillin V and amoxicillin are the treatment of choice for acute pharyngitis due to having a narrow spectrum of activity and are readily available, safe, and inexpensive. However, amoxicillin is often used instead of penicillin V due to the suspension being more palatable. Penicillin benzathine

is also an option but not favored due to causing more pain from administrating intramuscularly.

Chapter 131: Influenza

Jessica Njoku

KEY CONCEPTS

KEY CONCEPTS

① Influenza is a viral illness associated with high mortality and high hospitalization rates among persons older than 65 years. Aging of the population is contributing to an increased disease burden in the United States.

② Seasonal influenza epidemics are the result of viral antigenic drift, which is why the influenza vaccine is changed on a yearly basis. Antigenic drift forms the foundation of the recommendation for annual influenza vaccination.

③ The acquisition of a new hemagglutinin and/or neuraminidase by the influenza virus is called *antigenic shift*, which results in a novel influenza virus that has the potential to cause a pandemic.

④ The primary route of influenza transmission is person-to-person via inhalation of respiratory droplets, and transmission can occur for as long as the infected person is shedding virus from the respiratory tract.

⑤ Clinical diagnosis of influenza is difficult. Classic signs and symptoms include abrupt onset of fever, muscle pain, headache, malaise, nonproductive cough, sore throat, and rhinitis. These signs and symptoms usually resolve within 1 week of presentation.

⑥ In the United States, the primary mechanism of influenza prevention is annual vaccination. Vaccination not only prevents influenza illness and influenza-related hospitalizations and deaths but may also decrease healthcare resource use and the overall cost to society.

⑦ The inactivated influenza vaccine (IIV) and the live-attenuated influenza vaccine (LAIV) are commercially available for prevention of seasonal influenza. Both vaccines contain influenza A subtypes H3N2 and H1N1, and influenza B virus, which are initially grown in hens' eggs.

⑧ Antiviral drugs for prophylaxis of influenza should be considered adjuncts to vaccine and are not replacements for annual vaccination.

⑨ If used, antiviral drugs should be started within 48 hours of symptom onset to maximize effectiveness

⑩ Neurominidase inhibitors (oseltamivir, zanamivir, and peramivir) and cap-dependent endonuclease inhibitor (baloxavir) that have activity against both influenza A and influenza B viruses. Although the adamantanes inherently have activity against influenza A H1N1 viruses, they are no longer used clinically due to overwhelming viral resistance.

INTRODUCTION

Influenza causes significant morbidity and mortality, particularly among young children and the elderly. The Centers for Disease Control and Prevention (CDC) estimates that influenza has resulted in 9 to 45 million illnesses, 140,000 to 810,000 hospitalizations, and 12,000 to 61,000 deaths annually since 2010.[1,2] Globally, influenza causes nearly 650,000 deaths each year, with the highest burden among children younger than 5 years and adults 75 years and older.[3] More people die of influenza than of any other vaccine-preventable illness. Significant societal consequences associated with influenza include visits to physicians' offices and emergency departments and days lost from school and/or work. The societal costs associated with influenza are more than $10 billion in healthcare costs and $16.3 billion in indirect costs.[4]

Vaccination is the primary mechanism of influenza prevention in the United States. The antiviral armamentarium for treatment and prophylaxis of influenza is limited, which further emphasizes the importance of prevention with vaccination and appropriate use of infection control measures during outbreaks. Research toward the development of novel antivirals and vaccines is needed for effective control of seasonal epidemics and for pandemic preparedness.

ETIOLOGY AND EPIDEMIOLOGY

① Influenza infection can occur at any time during the year with the highest rates of influenza-associated illness during the winter months. The highest rate of infection occurs in children, but severe illness, hospitalization, and death occur most commonly among those older than 65 years, young children (younger than 2 years), and those with underlying medical conditions, including pregnancy and cardiopulmonary disorders, which increase their risk of complications from influenza. The seasonal influenza epidemics has resulted in an estimated 9.3 to 49 million influenza-related illnesses, 4.3 to 16.6 million healthcare visits, and between 12,000 and 79,000 deaths annually since 2010.[4] During 2019 to 2020 influenza season alone, influenza resulted in 39 to 56 million illnesses; 18 to 26 million medical visits; 410,000 to 740,000 hospitalizations, and 24,000 to 62,000 deaths.[5]

Influenza-associated illness was three times higher among children aged 0 to 4 years compared with those aged 5 to 17 years.[6] Similarly, influenza-associated illness rates among persons 65 years or older were nine times higher than those aged 18 to 49 years, and two times higher among those aged 50 to 64 years.[6] Furthermore, influenza-related hospitalization was highest among individuals age 65 years or older; 327 per 100,000 population.

Influenza activity was unusually low throughout the 2020 to 2021 influenza season both in the United States and globally, despite high levels of testing.[7] Between September 28, 2020, and May 22, 2021, in the United States, 0.2% of respiratory specimens tested by US clinical laboratories were positive for an influenza virus compared with 26.2% and 30.3% at the last three seasons. The low level of influenza activity at 0.8 per 100,000 population during this past season contributed to dramatically fewer influenza illnesses, hospitalizations, and deaths compared with previous seasons. Only one pediatric influenza death was reported during the 2020 to 2021 season compared to 37 (during 2011-2012) and 199 (during 2019-2020). COVID-19 mitigation measures such as wearing face masks, staying home, hand washing, school closures, reduced travel, increased ventilation of indoor spaces, and physical distancing, have contributed to the decline in 2020 to 2021 influenza incidence, hospitalizations, and deaths.[7] Influenza vaccination may also contributed to reduced illness during the 2020 to 2021 season; however, vaccine intake was not different compared to previous seasons.[8,9]

Vaccination coverage with ≥1 dose of flu vaccine was 58% among children aged 6 months to 17 years, while vaccination coverage among adults ≥18 years was 55%.[8–10] Vaccine coverage was highest among individuals aged 65 years or older (80%). Overall vaccine effectiveness was low at 39% (39% among individuals 65 years or older and 34% for children younger than 9 years).[11] Influenza vaccine effectiveness in 2020 to 2021 was not estimated due to low influenza virus circulation during the 2020 to 2021 influenza season. Deaths associated with influenza often result from secondary bacterial pneumonia, primary viral pneumonia, and/or exacerbation of underlying comorbidities.[12]

Influenza Viruses A, B, and C

Influenza virus types A, B, and C are members of the Orthomyxoviridae family and affect many species, including humans, pigs, horses, and birds. Influenza A and B viruses are the two types that cause disease in humans. Influenza A viruses are responsible for the regular, seasonal epidemics of the flu, whereas influenza B viruses are typically associated with sporadic outbreaks, particularly among residents of long-term care facilities. Influenza A viruses are further categorized into different subtypes based on changes in two surface antigens—hemagglutinin and neuraminidase (NA). Influenza B viruses are not categorized into subtypes.

Hemagglutinin allows the influenza virus to enter host cells by attaching to sialic acid receptors and is the major antigen to which antibodies are directed on exposure.[13] NA allows the release of new viral particles from host cells by catalyzing the cleavage of linkages to sialic acid.[14]

Sixteen hemagglutinin subtypes (H1-H16) and nine NA subtypes (N1-N9) of influenza A have been isolated from birds. However, the only influenza A subtypes that have circulated among humans since the 1918 pandemic (see Antigenic Drift and Antigenic Shift) are H1 to H3 and N1 and N2.[13] The primary subtypes of influenza A that have been circulating among humans for the past three decades are H3N2 and H1N1.

Antigenic Drift and Antigenic Shift

② Immunity to influenza virus occurs as a result of the development of antibody directed at the surface antigens, particularly hemagglutinin. However, immunity to one influenza subtype does not offer protection against other subtypes or types of influenza. Moreover, immunity to one antigenic variant of a subtype of influenza may not confer protection against other antigenic variants. Antigenic variants are created by point mutations in the surface antigens of a particular subtype, resulting in small changes in the hemagglutinin and/or NA molecules, which is called *antigenic drift*. Antigenic drift is the basis for seasonal epidemics of influenza, the reason for changes in the annual influenza vaccine, and the rationale behind the recommendation for annual vaccination.

③ Antigenic shift occurs when the influenza virus acquires a new hemagglutinin and/or NA via genetic reassortment rather than point mutations.[13] Most likely, the genetic reassortment occurs when an animal that supports the growth of multiple subtypes of influenza, such as a pig, is concurrently infected with two subtypes of the influenza virus. Conversely, antigenic shift may occur directly from avian strains that have gained competency in the human host. Antigenic shift results in the emergence of a novel influenza virus and carries the potential of causing a pandemic. However, novelty alone is insufficient to cause an influenza pandemic; the virus must be able to replicate in humans, spread person-to-person, and affect a susceptible population.[13] Immunity to one subtype of influenza does not confer protection against other subtypes or types.

Spanish Influenza of 1918

The influenza pandemic of 1918 was the most significant infectious disease outbreak known to humans, causing approximately 40 to 50 million deaths in a year, with more than 500,000 deaths occurring in the United States.[14] The pandemic originated in China, but occurred almost concurrently in Europe, Asia, and North America.[14]

The 1918 pandemic was caused by a particularly virulent influenza A H1N1 virus, which was entirely of avian origin.[14] In contrast to the other pandemics of the 20th century, the 1918 pandemic resulted in an unusual mortality pattern. The mortality peaked for those younger than 4 years, those between the ages of 25 and 35 years, and those older than 65 years, which resulted in a W-shaped mortality curve, as opposed to the U- or J-shaped curve typically associated with influenza.[11] Over half of the deaths occurred in persons aged 20 to 40 years. The death toll associated with this pandemic culminated in an almost 10-year drop in the life expectancy of the population at the time.[14]

Asian Influenza of 1957

The Asian flu pandemic began when a new H2 subtype of influenza A surfaced in Hunan province in China in 1957.[13] The virus formed from coinfection with an avian H2N2 virus and a human H1N1 virus in a common host, possibly a pig or a human. The H2N2 virus quickly spread to Japan, South America, the United States, New Zealand, and Europe, resulting in 1 to 2 million deaths worldwide, with 70,000 deaths occurring in the United States.[15] Unlike the Spanish influenza of 1918, the mortality curve for the Asian influenza pandemic was U- or J-shaped, with infants and elderly being most affected.

Hong Kong Influenza of 1968

The H2N2 virus of the Asian influenza circulated in the human population until 1968, when a new H3 subtype emerged in China and Hong Kong following genetic reassortment with the H2N2 virus.[13] The H3N2 virus quickly spread to the United States and later to Europe. This pandemic caused more than 30,000 deaths in the United States and 0.5 to 2 million deaths worldwide. The lower morbidity and mortality associated with the Hong Kong influenza may be explained by previous exposure of the population to the N2 subtype, and the availability of antibiotics for the management of secondary bacterial pneumonia. Similar to the Asian influenza of 1957, the mortality curve for the Hong Kong influenza pandemic was U- or J-shaped, primarily affecting infants and elderly.

Avian Influenza

Influenza viruses are in circulation in southern China during all months of the year.[13] Given this fact and the close proximity of dense populations of people, pigs, and wild and domestic birds, this area proves ideal for the emergence of new influenza viruses via genetic reassortment (antigenic shift) such as avian influenza. Avian influenza infections have been reported with A(H5N1), A(H5N6), A(H7N9), A(H9N2), A(H6N1), and A(H7N4) in China.[16]

The first report of human infection with the avian H5N1 virus occurred in 1997 in Hong Kong.[16] The virus reemerged in 2003 as an antigenically and genetically different virus that has spread widely through wild and domestic bird populations in Asia, Africa, and Europe as well as infecting humans in several countries.[17] From 2003 to 2021, 863 cases and 456 deaths caused by H5N1 infection have been reported. The overall case fatality was 53%.

The novel avian influenza H7N9 virus infection was first reported in humans in 2013, in China.[18] Since then, 1,568 laboratory-confirmed cases of human infection have been reported, including 615 deaths.[17] The majority of avian H7N9 human infection cases have been among those with recent exposure to live poultry or potentially contaminated environments, especially markets where live birds are sold.[18] The overall case fatality was 39%.

In December 2014, the first case of novel avian influenza H5N6 human infection was reported in China,[17] and to date, 25 laboratory-confirmed human cases of avian influenza A(H5N6) virus infection, including six deaths, were reported to World Health Organization (WHO) from China.[16,17]

The spread of avian influenza viruses from person to person is rare and has been limited, inefficient, and unsustained.[15–18] The precise mode of transmission is unknown, but most cases have occurred as a result of contact with poultry, contaminated environment, and prolonged personal contact.[16] Cases of transmission via aerosolization have not been reported.[16,17] Clinical presentation includes high fever and influenza-like illness, and watery diarrhea without blood may occur up to 1 week prior to respiratory symptoms.[15] Almost all patients have clinically apparent pneumonia. Progression to death, most commonly as a consequence of respiratory failure, occurs at a mean of 9 to 10 days after the onset of illness.[19] The NA inhibitors (oseltamivir, peramivir, and zanamivir) and cap-dependent endonuclease inhibitor (baloxavir marboxil) have activity against influenza A and B viruses (including H1N1), although higher doses of NA inhibitors may be needed for efficacy.[19–21] Two inactivated monovalent influenza vaccines, nonadjuvanted[22] and adjuvanted[23] influenza H5N1 vaccine and a H7N9[24] virus vaccine, are available for vaccination of persons 6 months and older. They are only available to government agencies and for stockpiles.[16] The recommended dose of the nonadjuvanted vaccine is two 1-mL injections given intramuscularly 28 days apart (range, 21-35 days) if 18 to 64 years old,[22] while the nonadjuvanted vaccine dose is two 0.5-mL injections given 21 days apart if adjuvanted vaccine if 18 to 64 years old, or two 0.25-mL injection given 21 days apart if 6 months to 17 years.[23] Individuals at high risk, for example, those who work with poultry and H5N1 poultry outbreak responders, are encouraged to receive annual seasonal influenza vaccine to minimize the risk of coinfection with human and avian influenza A viruses. The potential for avian viruses H5N1 and H7N9 to cause a pandemic is of concern as it could spread more quickly than pandemics of the past because of the mobility of people in today's world.

A severe pandemic, like that of 1918, could cause more than 10 million hospitalizations and more than 2 million deaths, whereas a moderate pandemic, like those of 1957 and 1968, could result in more than 1 million hospitalizations and more than 650,000 deaths in the United States alone.[25–27]

Swine Influenza of 2009

An outbreak of a novel influenza A H1N1 (formerly swine-origin influenza virus [SOIV]) was initially detected in Mexico in March 2009 and subsequently in the United States in April 2009 in California and Texas.[28] The virus then spread throughout North America, Europe, Asia, and subsequently worldwide, prompting the WHO on June 11, 2009, to declare phase 6, indicating widespread human infection, for the influenza pandemic.[29] Since 1998, triple reassortant swine influenza A (H1) viruses, containing genes from swine, avian, and human lineages, have circulated among swine in the United States.[15,28]

The virus, now formally known as influenza A(H1N1) pdm09, has become the predominant influenza A H1N1 in circulation, effectively replacing traditional seasonal influenza A (H1N1).

Several characteristics of the novel influenza A H1N1 outbreak differ from those of a typical seasonal influenza outbreak. Symptomatology associated with the novel influenza includes fever (94%), cough (92%), sore throat (66%), diarrhea (25%), and vomiting (25%).[28,30] An estimated 43 to 89 million cases of 2009 H1N1 occurred between April 2009 and April 2010 with a median of 274,000 hospitalizations. Globally, up to 575,000 H1N1-related deaths were reported; however, this may represent an underestimation of true disease burden.[27,29] The majority of the cases occurred in otherwise healthy children and adults younger than 65 years of age including pregnant women, with the highest incidence reported among those aged 18 to 64 years.[29] Contrary to seasonal influenza, where about 60% of hospitalizations and 90% of deaths occur in people older than or equal to 65 years, approximately 90% and 87% of 2009 H1N1-related hospitalizations and deaths, respectively, occurred in people younger than 65 years. However, like seasonal influenza, people with underlying health conditions had greater risk of hospitalizations and death. Among those who were deceased due to novel H1N1 infection, the median age was ~40 years and 59% of deaths (respiratory and cardiovascular) occurred in Southeast Asia and Africa.[29] The wide spread of 2009 novel influenza was attributed to extensive global trade and travel, such that the virus was detected in 122 countries in 6 weeks as opposed to 6 months with previous pandemics.[27]

Variant Influenza A (H3N2v) 2012

H3N2v is a nonhuman influenza virus that normally circulates in pigs and that has infected humans.[31] In 2011, the US Centers for Disease Control and Prevention (CDC) reported the first case of an influenza infection due to influenza A H3N2 variant virus (H3N2v).[31] Since then, 430 cases have been documented from 17 states resulting in 34 hospitalizations and low mortality.[32] The H3N2v is considered a variant virus because it is different from influenza A viruses circulating among humans. The H3N2v virus contains genes from avian, swine, and human viruses and the M gene from the 2009

H1N1 pandemic virus (A[H1N1]pdm09).[31,32] The virus spreads more readily from pigs to people than other variant viruses, but has limited person-to-person transmission. The main risk factor for infection with the virus based on evaluation of available cases is exposure to pigs, mostly at agricultural fairs.[32] Since the virus is related to human flu viruses from the 1990s, most adults have some immunity against it.[31] Hence, most cases to date have occurred in children, who have little immunity against this virus.[29,32]

The symptoms and severity of H3N2v have mostly been mild and similar to those of seasonal influenza (fever, cough, sore throat, body aches, etc.), but like seasonal influenza, serious illness with H3N2v infection is possible.[29] Vaccination remains key to preventing H3N2v infection. Additionally, the CDC has encouraged people at high risk of influenza complications to stay away from swine barns at fairs.[32] People who are at high risk of serious complications from influenza, including H3N2v virus infection, are children younger than 5 years, people aged 65 years or older, pregnant women, body mass index of 40 or higher, age less than 19 years of age on long-term aspirin- or salicylate-containing drugs, chronic care facility residents, and people with certain chronic medical conditions (asthma, cystic fibrosis, chronic obstructive pulmonary disease, diabetes, heart disease, stroke, sickle cell, kidney and liver disorders, inherited metabolic disorders, immunocompromised, and neurologic or neurodevelopmental conditions).[33] The treatment of H3N2v virus infection is similar to that of seasonal influenza. NA inhibitors and cap-dependent endonuclease inhibitors are the mainstay of treatment. The adamantanes should not be used due to high resistance.

PATHOGENESIS

④ The route of influenza transmission is person-to-person via inhalation of respiratory droplets, which can occur when an infected person coughs or sneezes.[30,34] Transmission may also occur if a person touches an object contaminated with respiratory secretions and then touches his or her mucus membranes. The incubation period for influenza ranges between 1 and 7 days, with an average of 2 days.[34] Transmission can occur for as long as the infected person is shedding virus from the respiratory tract. Adults are considered infectious within 1 day before until 7 days after onset of illness. Children, especially younger children, might potentially be infectious for longer periods (more than 10 days).[35,36] Viral shedding can persist for weeks to months in severely immunocompromised people.

The pathogenesis of influenza in humans is not well understood. The severity of the infection is determined by the balance between viral replication and the host immune response. Severe illness is likely a result of both a lack of ability of host defense mechanisms to inhibit viral replication and an overproduction of cytokines leading to tissue damage in the host.[16,30]

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Diagnosis of Influenza

General

- The clinical diagnosis of influenza can be difficult because the presentation is similar to a number of other respiratory illnesses. The sensitivity of clinical diagnosis ranges from 40% for children to 70% for adults and largely depends on the relative prevalence of influenza and other respiratory viruses circulating in a community.[34–36]
- The clinical course and outcome are affected by age, immunocompetence, viral characteristics, smoking, comorbidities, pregnancy, and the degree of preexisting immunity.[36]
- Complications of influenza may include exacerbation of underlying comorbidities, primary viral pneumonia, secondary bacterial pneumonia or other respiratory illnesses (eg, sinusitis, bronchitis, otitis), encephalopathy, transverse myelitis, myositis, myocarditis, pericarditis, and Reye's syndrome.[33,36]

Signs and Symptoms

- ⑤ Classic signs and symptoms of influenza include rapid onset of fever, myalgia, headache, malaise, nonproductive cough, sore throat, and rhinitis.[21,30,36]
- Nausea, vomiting, and otitis media are also commonly reported in children.[35]
- Signs and symptoms typically resolve in approximately 3 to 7 days, although cough and malaise may persist for more than 2 weeks.
- Primary viral pneumonia, occurring predominantly in pregnant women and those with underlying cardiovascular disease, usually begins with fever and dry cough, which changes to a productive cough of bloody sputum. This rapidly progresses to dyspnea, hypoxemia, and cyanosis with radiologic evidence of bilateral interstitial infiltrates.[36]
- Secondary bacterial pneumonia is usually seen in individuals with underlying pulmonary disorders and presents during the early stages of defervescence from the influenza infection. These patients usually present with fever, productive cough, and radiologic evidence of consolidation.[36]

Laboratory Tests

- Complete blood count and chemistry panels should be obtained to assess the overall status of the patient.
- The gold standard for diagnosis of influenza is reverse-transcription polymerase chain reaction (RT-PCR) or viral culture, which can provide information on the specific strain and subtype. Viral culture has a high sensitivity but can take as long as a week to develop, limiting the clinical relevance of the results.[36,37]

Other Diagnostic Tests

- Cultures of potential sites of infection should be obtained if coinfection, superinfection, or secondary infection is suspected.
- Chest radiograph should be obtained if pneumonia is suspected.

Influenza Diagnostics Tests

Influenza molecular assays

Rapid influenza molecular assays (RIMAs) detect influenza viral RNA in upper respiratory tract specimens utilizing different nucleic acid amplification technologies (NAATs). They have high sensitivity (90%-95%) and high specificity (55%-99%), depending on the virus type, compared with RT-PCR assays.[38] FDA-cleared RIMAs are available for point of care (POC) use that produce results in approximately 15 to 30 minutes.

RT-PCR (real time or multiplex) is a nucleic acid amplification test that can identify the presence of influenza viral RNA or nucleic acids in respiratory specimens with high sensitivity and specificity. It is the most sensitive, specific, and versatile diagnostic test for influenza.[37] Results are available in approximately 45 minutes to several hours (1-6 hours) depending upon the assay, and are frequently used as a confirmatory test.

Rapid influenza diagnostic tests (RIDTs)

RIDTs use enzyme immunoassay (EIA) technology to provide results within 10 to 15 minutes and may have utility in community- and hospital-based outpatient settings because of their rapid processing times. RIDTs allow for differentiation of influenza viruses A and B but none of the RIDTs provide any information about influenza A virus subtypes. Sensitivities for RIDTs range are low often yielding false-negative results, while specificities are high compared with RT-PCR or viral culture.[37,38] For this reason, RIDTs are not recommended for use in hospitalized patients with suspected influenza, and RIMAs are preferred in outpatient settings since CLIA-waived tests are available for POC use.

Immunofluorescence assays (IFAs)

IFAs are antigen detection assays that generally require use of a fluorescent microscope to produce results in approximately 2 to 4 hours with moderate sensitivity and high specificity. One rapid IFA is an RIDT and utilizes an analyzer device to produce results in approximately 15 minutes.[37]

Viral culture

Culture allows for extensive antigenic and genetic characterization of influenza viruses. However, viral culture results do not yield timely results to inform clinical management. Shell-vial tissue culture results may take 1 to 3 days, while traditional tissue-cell viral culture results may take 3 to 10 days.

Serologic testing

Routine serological testing for influenza requires paired acute and convalescent sera, does not provide timely results to help with clinical decision-making, is only available at a limited number of public health or research laboratories and is not generally recommended, except for research and public health investigations.

Specimen Collection

Upper respiratory tract specimens should be collected from outpatients for influenza testing as soon after illness onset as possible, preferably within 4 days of symptom on-set to increase detection of influenza viruses. Nasopharyngeal specimens are preferred over other upper respiratory tract specimens. If nasopharyngeal specimens are not available, nasal and throat swab specimens should be collected and combined together for influenza testing over single specimens from either site (particularly over throat swabs). Collect endotracheal aspirate or bronchoalveolar lavage fluid specimens from hospitalized patients with respiratory failure receiving mechanical ventilation, including patients with negative influenza testing results on upper respiratory tract specimens, for influenza testing.

PREVENTION

The best means to decrease the morbidity and mortality associated with influenza is to prevent infection through vaccination.[34,35] Appropriate infection control measures, such as hand hygiene, basic respiratory etiquette (eg, cover your cough, throw tissues away), and contact avoidance, are important in preventing the spread of influenza. Additionally, chemoprophylaxis is useful in certain situations.

Vaccination

⑥ The primary means of influenza prevention used in the United States is annual vaccination. Vaccination can help prevent hospitalization and death among those at high risk, decrease influenza-like illness, decrease visits to physicians' offices and emergency rooms, decrease otitis media in children, and prevent school and/or work absenteeism. Annual vaccination is recommended for all persons aged 6 months or older and caregivers (eg, parents, teachers, babysitters, nannies) of children younger than 6 months. Vaccination is also recommended for those who live with and/or care for people who are at high risk, including household contacts and healthcare workers.

The ideal time for all influenza vaccination is during October or November to allow for the development and maintenance of immunity during the peak of the influenza season.[34,35] Table 131-1 lists the vaccination coverage rates and goals for various patient populations. Provider recommendation and offer of vaccination was associated with significantly higher vaccine uptake among adults 18 years and older (67%), compared to providers who only recommended but did not offer (48%), and those who neither recommended nor offered (32%).[39] If vaccination rates improved to the Healthy People goal of 70% for all age groups, another 4.6 million illnesses, 2.2 million medical visits, and 65,844 hospitalizations could have been prevented during the 2020 to 2021 influenza season.[10] Vaccine efficacy is highest when influenza virus in circulation is well matched with strains in the vaccine. Mismatched seasons have occurred, and were associated with reduced influenza vaccine uptake and severe influenza infection. TIV (vaccine efficacy 52% vs matched 65%) and LAIV (vaccine efficacy 54% vs matched 83%) provide cross protection against nonmatching circulating strains.[40]

TABLE 131-1

Influenza Vaccination Rates and Goals by Patient Population

Patient Population	Vaccination Coverage (%) 2020-2021	Vaccination Coverage National Goal (2030) (%)
Children aged 6 months to 17 years	58	70
Persons aged 18 years or older	55	70
Nursing home residents	72 (2019-2020)	90
Pregnant women	61	80
Healthcare workers	90 (2018-2019)	90

Data from References 8–10.

7 The two vaccine types available for prevention of seasonal influenza are the inactivated influenza vaccine (IIV), and the live attenuated influenza vaccine (LAIV).[34] IIV is available as trivalent (IIV3) and quadrivalent (IIV4) formulations, while LAIV is a quadrivalent formulation. Both vaccines contain two influenza A subtypes (H3N2 and H1N1) and two influenza B viruses; the specific strains included in the vaccine each year change based on antigenic drift. The viruses used for both vaccines are initially grown in embryonated hens' eggs, which explains the precautionary measures for vaccination of persons with a severe allergic reaction to eggs.[34] Two other vaccines are produced using non-egg based technologies, recombinant quadrivalent vaccine [RIV4 (Flublok® Quadrivalent)] and cell-culture quadrivalent vaccine [ccIIV4 (Flucelvax Quadrivalent®)], and are safe if the patient has egg allergy. The Advisory Committee on Immunization Practices (ACIP) has made the following recommendations regarding the vaccinations of persons with reports of egg allergy: 1) for persons with a history of severe allergic reaction (eg, anaphylaxis) to any egg-based IIV or LAIV of any valency, the provider can consider administering ccIIV4 or RIV4; 2) for persons with a history of severe allergic reaction (eg, anaphylaxis) to any ccIIV of any valency, the provider can consider administering RIV4; and 3) for persons with a history of severe allergic reaction (eg, anaphylaxis) to any RIV of any valency, the provider can consider administering ccIIV4. Providers can also consider consulting with an allergist to help determine which vaccine component is responsible for the allergic reaction.[34] The CDC encourages individuals to use the Vaccine Adverse Event Reporting System to aide in collecting and analyzing adverse events following influenza vaccinations.[31]

Trivalent and Quadrivalent Influenza Vaccine

7 Intramuscular IIV is FDA approved for use in people aged 6 months and older regardless of their immune status. For adults and older children, the deltoid is the preferred injection site. Infants and younger children should be vaccinated in the anterolateral thigh. Several commercial products are available and are approved for different age groups (Table 131-2). IIV is made with killed viruses, meaning it cannot cause signs and symptoms of influenza-like illness (Table 131-3). Age and immune status can affect the efficacy of IIV as can the similarity of the vaccine to the viruses in circulation. Fluzone quadrivalent may be given to children aged 6 to35 months as either 0.25 mL per dose or 0.5 mL per dose. No preference is expressed for one or

the other dose volume for this age group. Persons aged ≥3 years should receive 0.5-mL dose volume.[34] Flucelvax® quadrivalent vaccine use has been expanded to include those aged 6 months and older, and is reformulated without egg protein.[34]

TABLE 131-2

Approved Influenza Vaccines for Different Age Groups—United States, 2021-2022 Season

Vaccine	Trade Name	Manufacturer	Dose/Presentation	Thimerosal Mercury Content (µg Hg/0.5 mL dose)	Age Group	Number of Doses
Quadrivalent IIV (IIV4)						
IIV4	Afluria Quadrivalent	Seqirus	0.25-mL prefilled syringe 0.5-mL prefilled syringe 5-mL multidose vial	0 0 24.5	≥ 6-35 months ≥ 3 years ≥ 6 months (needle/syringe) or 18-64 years via jet injector	1 or 2[a] 1 or 2[a] 1 or 2[a]
IIV4	Fluarix Quadrivalent	GlaxoSmithKline	0.5-mL prefilled syringe	0	≥ 6 months	1 or 2[a]
IIV4	FluLaval Quadrivalent	GlaxoSmithKline	0.5-mL prefilled syringe 5-mL multidose vial	0 <25	≥ 6 months ≥ 6 months	1 or 2[a]
IIV4	Fluzone Quadrivalent[b]	Sanofi Pasteur	0.25-mL prefilled syringe 0.5-mL prefilled syringe 0.5-mL single-dose vial 5-mL multi-dose vial	0 0 0 25	≥6-35 months ≥ 6 months ≥ 6 months ≥ 6 months	1 or 2[a] 1 or 2[a] 1 or 2[a] 1 or 2[a]
Quadrivalent IIV High Dose (IIV4-HD)						
aIIV4 high dose	Fluad Quadrivalent	Seqirus	0.5 mL prefilled syringe	0	≥65 years	1
IIV4 high dose	Fluzone HD Quadrivalent	Sanofi Pasteur	0.7-mL prefilled syringe	0	≥65 years	1

Cell culture-based quadrivalent IIV (ccIIV4)						
ccIIV4	Flucelvax Quadrivalent	Seqirus	0.5-mL prefilled syringe 5-mL multidose vial	0 25	≥2 years ≥2 years	1 or 2[a] 1 or 2[a]
Recombinant quadrivalent IIV (RIV4)						
RIV4	Flublok Quadrivalent	Sanofi Pasteur	0.5-mL prefilled syringe	0	≥18 years	1
LAIV Quadrivalent (LAIV4)						
LAIV	FluMist Quadrivalent	AstraZeneca	0.2-mL sprayer	0	2-49 years	1 or 2[c]

[a] Two doses administered at least 4 weeks apart are recommended for children aged 6 months to less than 9 years who are receiving influenza vaccine for the first time or received one dose in the first year of vaccination during the previous influenza season.

[b] Fluzone quadrivalent may be given to children aged 6 to 35 months as either 0.25 mL per dose or 0.5 mL per dose. No preference is expressed for one or the other dose volume for this age group. Persons aged ≥3 years should receive 0.5-mL dose volume.

[c] Two doses administered 4 weeks apart are recommended for children aged 2 years to less than 9 years who are receiving influenza vaccine for the first time.

IIV, inactivated influenza vaccine; aIIV4, adjuvanted inactivated influenza vaccine, quadrivalent, high dose; IIV4, inactivated influenza quadrivalent vaccine; IIV4-HD, inactivated influenza quadrivalent vaccine – high dose; ccIIV4, cell culture-based quadrivalent influenza vaccine; RIV4, recombinant quadrivalent influenza vaccine; LAIV, live-attenuated influenza vaccine.

Note:

- IIVs and RIV4 may be administered concomitantly or sequentially with other inactivated vaccines or live vaccines. LAIV4 may be given simultaneously with other live or inactivated vaccines. However, after administration of a live vaccine (such as LAIV4), at least 4 weeks should elapse before another live vaccine is administered.
- Influenza antiviral medications might reduce the effectiveness of LAIV4 if given within 48 hours before to 14 days after administration of LAIV4. Persons who receive influenza antiviral medications within this period of LAIV4 vaccination can be revaccinated with another appropriate influenza vaccine (eg, IIV or RIV4).

Data from References 34,35.

TABLE 131-3

Comparison of Inactivated Influenza Vaccine (IIV) and Live-Attenuated Influenza Vaccine (LAIV)

Characteristic	IIV (IIV3/IIV4)	LAIV
Age groups approved for use	≥6 months	2-49 years
Immune status requirements	Immunocompetent or immunocompromised	Immunocompetent
Viral properties	Inactivated (killed) influenza A (H3N2), A (H1N1), and B viruses	Live-attenuated influenza A (H3N2), A (H1N1), and B viruses
Route of administration	Intramuscular	Intranasal
Immune system response	High serum IgG antibody response	Lower IgG response and high serum IgA mucosal response

Data from References 34,35.

In children aged between 6 and 24 months, a 2-year randomized study of intramuscular IIV3 exhibited 89% seroconversion and efficacy of 66% in year 1 and 7% in year 2 versus culture-confirmed influenza.[41] In children aged between 2 and 15 years, the efficacy of IIV3 was 91% and 77% against culture-confirmed influenza A H1N1 and H3N2, respectively. IIVs reduced the risk of influenza and influenza-like illness (ILI) in children.[42] To prevent one case of influenza, five children would need to be vaccinated, and to prevent one case of ILI, 12 children would need to be vaccinated. Therefore, vaccinating children could prevent influenza-related mortality and may also lead to fewer parents taking time off work. Two doses of IIVs are important for children under the age of 9 years, supporting the rationale for the recommendation of a booster dose of IIV at least 4 weeks after the initial dose in children between 6 months and less than 9 years of age if no previous vaccination (see Table 131-2).[34]

IIV is also effective in adult populations under and older than the age of 65 years. Intramuscular IIVs demonstrated a reduction in influenza, ILI, hospitalization, and work absenteeism in healthy adults aged 16 to 65 years.[43] Seventy-one adults would need to be vaccinated to prevent one influenza case, and 29 adults need to be vaccinated to prevent one ILI. In pregnant women, IIVs efficacy was 50% (number needed to vaccinate, NNV 55), and 49% in infants up to 24 weeks (NNV 56).

Adults older than the age of 65 years benefit from influenza vaccination, including prevention of complications, decreased risk of influenza-related hospitalization, and death.[44] However, people in this population may not generate a strong antibody response to the vaccine and may remain susceptible to infection. In patients older than the age of 60 years who do not reside in a long-term care facility, IIV efficacy was 58% against influenza illness.[45] Although the efficacy against influenza illness for those living in long-term care facilities is between 30% and 40%, the vaccine is 50% to 60% effective in preventing influenza-related hospitalization or pneumonia and 80% effective in preventing influenza-related death.[45]

Fluzone HD trivalent induced higher immune response compared with standard IIV3 and offered better protection than SD-IIV3 for persons aged 65 years or older. Fluzone HD prevented 24% more cases of influenza caused by any circulating influenza strain and 51% more cases of influenza caused by strains similar to those contained in the vaccine compared to standard trivalent vaccine. Compared to IIV3, Fluzone HD trivalent would avert 195,958 cases of influenza, 22,567 influenza-related hospitalizations, 5423 influenza-related deaths, and generate 29,023 more Quality Adjusted Life Years among US seniors.[46] Fluzone HD quadrivalent or Fluad quadrivalent vaccine are preferred vaccines for use in adult patients 65 years and older.[35]

The most frequent adverse effect associated with IIV is soreness at the injection site that lasts for less than 48 hours. IIV may cause fever and malaise in those who have not previously been exposed to the viral antigens in the vaccine.[34] Allergic-type reactions (hives, systemic anaphylaxis) rarely occur after influenza vaccination and are likely a result of a reaction to residual egg protein in the vaccine.

The 1976 swine influenza vaccine was linked to a rise in the incidence of Guillain-Barré syndrome (GBS), and this has propagated the belief that IIV may cause GBS.[47] However, there is insufficient evidence to establish causality. Although several studies have failed to establish a relationship between influenza vaccination and increased frequency of GBS, some studies have demonstrated a small but significant increase in GBS following influenza vaccination.[47] Therefore, vaccination should be avoided in persons who are not at high risk for influenza complications and who have experienced GBS within 6 weeks of receiving a previous influenza vaccine.[34] The potential benefits of influenza vaccination in terms of prevention of severe illness, hospitalization, and mortality significantly outweigh the risks of GBS, and vaccination is recommended for all groups previously discussed.

The multidose vials and a few of the single-dose preparations of intramuscular IIV contain trace to small amounts of a preservative, thimerosal, which is a mercury-containing compound (see Table 131-2). Some individuals are concerned about thimerosal exposure, particularly among children, because of the unfounded belief that thimerosal exposure is linked to the development of autism. No scientifically persuasive evidence exists to suggest harm from thimerosal exposure from a vaccine. Conversely, accumulating evidence reports the lack of harm from such exposure.[48,49] Thus, similar to GBS, the potential benefits of influenza vaccination in terms of prevention of severe illness, hospitalization, and mortality significantly outweigh the theoretical risk associated with thimerosal exposure, and vaccination is recommended for all groups previously discussed. However, to maximize the public health benefit and placate concerned individuals, thimerosal-free vaccine is available (see Table 131-2).

Live-Attenuated Influenza Vaccine

⑦ LAIV is made with live, attenuated viruses and is approved for intranasal administration in healthy people between 2 and 49 years of age (see Table 131-3). Advantages of LAIV include its ease of administration, intranasal rather than intramuscular administration, and the potential induction of broad mucosal and systemic immune response.[34] The mucosal response occurs at the site of viral entry and may prevent infection before viral replication occurs. LAIV is more expensive than IIV and is approved for use in a more limited population. Originally licensed as a trivalent vaccine, in 2012, the FDA approved FluMist® Quadrivalent vaccine (LAIV4) for influenza prevention in people aged 2 to 49 years.[34] FluMist® Quadrivalent vaccine which has replaced the trivalent vaccine contains four strains of the influenza viruses, two influenza A strains and two influenza B strains. The inclusion of a second B strain in the vaccine increases the likelihood of adequate protection against circulating influenza B strains.

Studies of FluMist® trivalent, in addition to three new clinical trials with the quadrivalent vaccine in 4,000 children (2-17 years) and adults (18-49 years) in the United States, provide supporting evidence on the efficacy and safety of FluMist® Quadrivalent.[50] Immune responses were similar between FluMist® Quadrivalent and FluMist® trivalent. LAIV4 recipients aged 2 to 5 years had 52.5% and 54.4% fewer cases of influenza illness against matched and mismatched strains, respectively, as compared with IIV3 recipients.[50]

Although LAIV4 is FDA approved for adults younger than the age of 49 years, LAIV is effective in healthy adults aged between 18 and 64 years.[34] LAIV4 should not be used during pregnancy. Vaccination reduced the number of severe febrile illnesses by 18.8% and febrile upper respiratory tract illnesses by 23.6%.[50] Additionally, vaccination led to fewer days of illness, fewer days lost from work, fewer visits to healthcare providers, and decreased use of prescription antibiotics and nonprescription medications.[50]

Adverse reactions of LAIV are similar among those receiving FluMist® Quadrivalent and FluMist® trivalent. The adverse effects typically associated with LAIV administration include runny nose, congestion, sore throat, and headache. Because LAIV contains live, attenuated viruses, viral shedding may occur for several days following vaccination with LAIV, although this should not be equated with person-to-person transmission.[34] Additionally, because LAIV contains live, attenuated viruses, which carry a theoretical infection risk, LAIV should not be given to immunosuppressed patients or given by healthcare workers who are severely immunocompromised. Moreover, for the reasons discussed in IIV above, LAIV should not be administered to persons with a history of GBS or hypersensitivity to eggs. Vaccine effectiveness of LAIV was 45% against influenza A and B, with 25% protection against influenza A (H1N1) pdm09 compared with unvaccinated children.[34] LAIV is not recommended in several populations, including people older than 50 years and pregnant females, largely because the vaccine has not been studied extensively in these populations. However, many clinicians believe the use of LAIV in these populations is acceptable.[34,50]

Postexposure Prophylaxis

⑧ Antiviral drugs available for prophylaxis of influenza should be considered adjuncts but are not replacements for annual vaccination. Adamantanes are no longer recommended for prophylaxis or treatment in the United States because of widespread resistance among influenza viruses.[35,51] Neuraminidase (NA) inhibitor antiviral medications are approximately 70% to 90% effective in preventing influenza against susceptible influenza viruses and are useful adjuncts to influenza vaccination.[52] Peramivir is not approved for chemoprophylaxis; however, oseltamivir and zanamivir are effective prophylactic agents against influenza for preventing laboratory-confirmed influenza when used for seasonal prophylaxis (67% and 85% effective for zanamivir and oseltamivir, respectively) and preventing influenza illness among persons exposed to a household contact who was diagnosed with influenza (79%-81% and 68%-89% effective for zanamivir and oseltamivir, respectively). Additionally, oseltamivir was 92% effective against influenza, and also reduced associated complications when used as seasonal prophylaxis among immunized, institutionalized, elderly patients.[35,52] Zanamivir and oseltamivir are 79% to 81% and 68% to 89% effective, respectively, in preventing influenza illness among persons exposed to a household contact who was diagnosed with influenza.[34,51] In 2020, the FDA approved baloxavir for post-exposure prophylaxis of influenza in persons aged 12 years and older.[52] Baloxavir, when administered within 24 hours of the onset of symptoms in persons 12 years of age and older, reduced the risk of household transmission of influenza by 86% compared with placebo.[53] Prophylaxis was begun within 2 days after exposure. Oseltamivir is FDA approved for chemoprophylaxis in individuals aged 1 year and older. However, the CDC, the American Academy of Pediatrics (AAP), and the Pediatric Infectious Diseases Society (PIDS) provide an expanded recommendation for chemoprophylaxis in those aged 3 months and older.[35,51] All of these agents remain active against all influenza viruses, including influenza A H3N2v. Table 131-4 lists dosing recommendations.

TABLE 131-4

Recommended Daily Dosage of Influenza Antiviral Medications for Treatment and Prophylaxis—United States

Drug	Adult Treatment	Adult Prophylaxis[a]	Pediatric Treatment	Pediatric Prophylaxis[a]
CAP-dependent endonuclease inhibitor				
Baloxavir[b,c]	12 yrs and older: 40 to <80 kg: One 40 mg dose >80 kg: One 80 mg dose	None	FDA approved and recommended for use in children aged 12 yrs or older weighing at least 40 kg. See adult dosage	None
Neurominidase inhibitors				
Oseltamivir[d,e,f]	75-mg capsule twice daily × 5 days	75-mg capsule daily × 10 days	Term infants 0-8 months: 3 mg/kg/dose twice daily 9-11 months[g]: 3.5 mg/kg/dose twice daily or 3 mg/kg/dose twice daily ≥1 year: ≤15 kg: 30 mg twice daily >15-23 kg: 45 mg twice daily >23-40 kg: 60 mg twice daily >40 kg: 75 mg twice daily Duration: All for 5 days	Not recommended if <3 months 3 to <12 months, 3 mg/kg/dose daily 9-11 months, 3.5 mg/kg/dose daily ≥1 year: ≤15 kg: 30 mg daily >15-23 kg: 45 mg daily >23-40 kg: 60 mg daily >40 kg: 75 mg daily Duration: All for 10 days
Zanamivir	10 mg (2 of 5 mg inhalations) twice daily × 5 days	10 mg (2 of 5 mg inhalations) daily × 10 days	10 mg (2 of 5 mg inhalations) twice daily × 5 days for ≥7 years old	10 mg (2 of 5 mg inhalations) daily for ≥ 5 years old × 10 days
Peramivir[c,e]	13 yrs and older: One 600 mg dose via intravenous infusion for 15-30 minutes	None	2 to 12 yrs of age: One 12 mg/kg dose, up to 600 mg maximum, via intravenous infusion for a minimum of 15-30 minutes	None

[a] If influenza vaccine is administered, prophylaxis can generally be stopped 14 days after vaccination for noninstitutionalized persons. When prophylaxis is being administered following an exposure, prophylaxis should be continued for 10 days after the last exposure. In persons at high risk for complications from influenza for whom vaccination is contraindicated or expected to be ineffective, chemoprophylaxis should be continued for the duration that influenza viruses are circulating in the community during influenza season.

[b] Time to peak = 4 hours. Food and cations (calcium, aluminum, magnesium, iron) can decrease peak concentration by 48%. Long half-life (79.1 hours) and is

metabolized by UDP-glucuronosyltransferase (UGT1A3) and CYP3A4.

[c] For the treatment of uncomplicated influenza with oral baloxavir or intravenous peramivir, a single dose is recommended. Longer daily dosing (oral oseltamivir or intravenous peramivir) can be considered for patients who remain severely ill after 5 days of treatment.

[d] Oseltamivir dosing for preterm infants using their postmenstrual age (ie, gestational age + chronological age): <38 weeks: 1.0 mg/kg/dose twice daily; 38–40 weeks: 1.5 mg/kg/dose twice daily; >40 weeks: 3.0 mg/kg/dose twice daily.[32]

[e] In patients with renal insufficiency, the dose should be adjusted on the basis of creatinine clearance. See https://www.cdc.gov/flu/professionals/antivirals/summary-clinicians.htm.[33,52]

[f] Some experts recommend 150 mg twice daily for severe illness in pregnant women. Optimal dosing for prophylaxis in pregnant women is unknown.[33]

[g] The American Academy of Pediatrics recommends 3.5 mg/kg per dose twice daily; CDC and US Food and Drug Administration (FDA)–approved dosing is 3 mg/kg per dose twice daily for children aged 9 to 11 months.[32,54]

Note: Although amantadine and rimantadine have been used historically for the treatment and prophylaxis of influenza A viruses, due to high resistance, the CDC no longer recommends the use of these agents for the treatment and/or prophylaxis of influenza.

Data from References 35,52.

In those patients who did not receive the influenza vaccination and are receiving an antiviral drug for prevention of disease during the influenza season, the medication should optimally be taken for the entire duration of influenza activity in the community. The use of prophylaxis requires clinical judgment and depends on a variety of factors, but prophylaxis for seasonal influenza should be considered during influenza season for the following groups of patients after exposure to an infectious source[35,36,51]:

1. Persons at high risk of serious illness and/or complications who are exposed to an infectious person and cannot be vaccinated.
2. Persons at high risk of serious illness and/or complications who are vaccinated but exposed to an infectious person during the first 2 weeks following vaccination. The development of sufficient antibody titers after vaccination takes approximately 2 weeks.
3. Persons with severe immune deficiency or who may have an inadequate response to vaccination (eg, advanced human immunodeficiency virus [HIV] disease, persons receiving immunosuppressive medications), after exposure to an infectious person.
4. Long-term care facility residents, regardless of vaccination status, when an outbreak has occurred in the institution.

LAIV should not be administered until 48 hours after influenza antiviral therapy has stopped, and influenza antiviral drugs should not be administered for 2 weeks after the administration of LAIV because the antiviral drugs inhibit influenza virus replication.[34,36] No contraindication exists for concomitant use of IIV and influenza antiviral drugs. If chemoprophylaxis is given, it should be administered as soon as possible after exposure, ideally no later than 48 hours after exposure.[36] Postexposure prophylaxis should not be given if >48 hours has elapsed since exposure, and full-dose empiric antiviral treatment should be initiated as soon as symptoms occur, if treatment is indicated. Duration of chemoprophylaxis in a non-outbreak setting is 7 days after the most recent exposure to a close contact with influenza.[36,51]

Pregnant Females and Immunocompromised Hosts

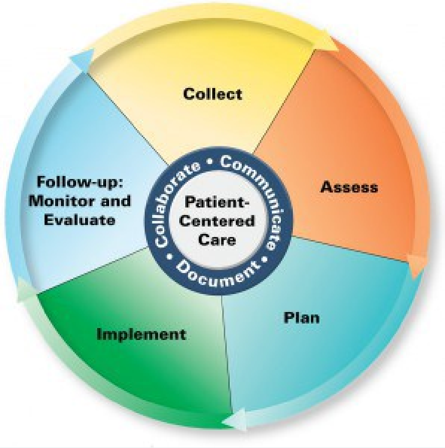
Pregnant females and immunocompromised hosts are special populations at increased risk of influenza complications and are also populations in whom careful consideration must be given in regard to prevention strategies.

Pregnant females, regardless of trimester, should receive annual influenza vaccination with IIV but not with LAIV.[34,36] No studies have demonstrated an increased incidence of adverse effects in mothers or their infants related or potentially related to IIV, but no such data exist for LAIV.[34] Receipt of an influenza vaccination reduced hospitalizations of pregnant females by about 40%.[55] Influenza vaccination of pregnant females reduced hospitalization of their infants by 92% during the first 6 months of life.[54] IIV is also safe for breastfeeding mothers. No data exist for LAIV and breastfeeding mothers, but caution is warranted because of the potential for viral shedding.[34]

Immunocompromised hosts should receive annual influenza vaccination with IIV but not with LAIV. IIV was 100% effective against laboratory-confirmed influenza in HIV-positive patients with no significant effect on viral load or CD4 cell count.[56] HIV-infected persons may benefit from vaccination with high-dose IIV3 due to greater immunogenicity compared to standard-dose vaccine (H1N1, seroprotection rate; 96% vs 87%).[56] In solid-organ transplant recipients high-dose IIV3 (compared with standard dose IIV) resulted in higher immunogenicity.[57] A two-dose vaccination strategy spaced 5 weeks apart in solid-organ transplant recipients elicited greater immune response compared to single dose.[58] Although this suggests a potential benefit from a two-dose regimen, such a regimen is not recommended for solid-organ transplant recipients. Standard annual influenza vaccination and early antiviral therapy were shown to reduce influenza-related morbidity in transplant recipients (solid and hematopoietic).[59] Immune responses in patients receiving chemotherapy for either solid or hematologic tumors are lower (fourfold rise, 17%-52%) than in those who had completed chemotherapy (50%-83%) and healthy patients (67%-100%).[60] However, there was lower mortality- and infection-related outcomes with influenza vaccination of immunocompromised adults with cancer.[61]

Large clinical trials evaluating the use of influenza antivirals for prophylaxis are lacking in immunocompromised hosts. Viral shedding occurs for prolonged periods in this population and may promote the development of antiviral resistance, which has been documented with oseltamivir in immunocompromised patients.[35,36]

Patient Care Process for Influenza Infection Treatment



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics: age, occupation, travel, lifestyle, immune status, present and past medical history, allergies
- Medication history (include prescription, nonprescription, and other substances); vaccination history; pregnancy status
- Microbiologic results from rapid respiratory viral panel and secondary bacterial infection. Bacterial susceptibility tests when available (see Clinical Presentation: Diagnosis of Influenza)
- Laboratory results, major organ function (particularly, kidney and liver), lactate

Assess

- Assess for medication contraindications and drug interactions
- Determine severity of illness based on vital signs, acute organ dysfunction, and source control (or lack thereof) (see Clinical Presentation: Diagnosis of Influenza)
- Determine at-risk patients for secondary bacterial infection of the respiratory tract, patient’s microbiologic history, previous antibiotic

exposure, and response to current therapy (see Clinical Presentation: Diagnosis of Influenza)

- Determine if other conditions are present such as chronic lung disease likely to affect outcomes of infection
- Estimate creatinine clearance for drug dosing

Plan*

- Strongly recommend future influenza vaccine if no contraindication is present (Tables 131-2 and 131-3)
- Initiate treatment neuraminidase therapy—oral or inhaled or IV based on severity of illness (Table 131-4)
- Determine influenza treatment goals of therapy with monitoring parameters for each goal (see Goals of Therapy)
- Determine appropriate antibiotic therapy for secondary bacterial infection and monitoring plan
- Establish antimicrobial monitoring goals for efficacy (eg, resolution of infection, clearance of bacteria from blood cultures) and drug toxicity
- Check for drug interactions and dose adjustments based on end-organ function

Implement

- Initiate a neuraminidase inhibitor and continue for ~7 days after identification of illness onset in the last patient (prophylaxis for community outbreak) or 5 days (treatment) or establish a tentative stop date for severely ill patients
- If secondary bacterial infection is suspected, initiate empiric antimicrobial regimen, and deescalate antimicrobial therapy to more narrow-spectrum agents as appropriate based on response and microbiologic data
- Assess patient as needed for response to antiviral medications, and other treatments
- Use measures to minimize adverse events to medications and assess for occurrence of adverse events

Follow-up: Monitor and Evaluate

- Refer patient for other health, wellness, or follow-up services to their identified primary care provider or another provider (provide patient with documentation of referral)
- Determine if patient shows improvement in the signs and symptoms of infection within 48 hours after neuraminidase inhibitor is initiated
- Monitor for emergence of resistant virus.
- Monitor for occurrence of secondary bacterial pneumonia

**Collaborate with patient, caregiver(s), and other healthcare professionals.*

TREATMENT

When prevention efforts fail or are not used, clinicians must turn to the agents available for treatment of influenza. Antiviral treatment options are limited, particularly in the face of resistance to the adamantanes and oseltamivir. The four primary goals of therapy of influenza are to control symptoms, prevent complications, decrease work and/or school absenteeism, and prevent the spread of infection.

General Approach to Treatment

⑨ In the era of pandemic preparedness and increasing resistance, early and definitive diagnosis of influenza is crucial. Antiviral drugs are most effective if started within 48 hours of the onset of illness. Moreover, the sooner the antiviral drugs are started after the onset of illness, the more effective they are. Antiviral drugs shorten the duration of illness and provide symptom control. Adjunct agents, such as acetaminophen for fever or an antihistamine for rhinitis, may be used concomitantly with the antiviral drugs.

Nonpharmacologic Therapy

Patients suffering from influenza should get adequate sleep and maintain a low level of activity. They should stay home from work and/or school to rest and prevent the spread of infection. Appropriate fluid intake should be maintained. Cough/throat lozenges, warm tea, or soup may help with symptom control (cough, sore throat).

Pharmacologic Therapy

The Cap-dependent endonuclease inhibitor, baloxavir and NA inhibitors, oseltamivir, zanamivir, and peramivir are the only antiviral drugs available for the treatment and prophylaxis of influenza.[51] Peramivir is the only intravenous formulation commercially available. The adamantanes (amantadine and rimantadine) are no longer recommended due to high resistance among influenza viruses. A limited discussion of adamantanes can be found in the following section, but the focus will be on oseltamivir, zanamivir, and peramivir.

Adamantanes

The adamantanes (amantadine and rimantadine) block the M2 ion channel, which is specific to influenza A viruses, and inhibit viral uncoating. Historically, the adamantanes were used for the treatment of seasonal influenza A H1N1, as they do not have activity against influenza A H3N2 or influenza B viruses. The novel influenza A H1N1 that emerged during the 2009 to 2010 influenza season, which has now replaced seasonal influenza A H1N1 as the predominant seasonal virus, was resistant to the adamantanes. Since 2009 more than 99% of influenza A H3N2 and H1N1pdm09 were resistant to adamantanes.[51] As a result, the CDC only recommends the use of NA inhibitors for the treatment and prophylaxis of influenza A, until susceptibility of adamantanes is reestablished among influenza A viruses. Resistance to adamantanes is often conferred by a single-point mutation, and this is problematic because it results in cross-resistance to the entire class.[36]

Cap-Dependent Endonuclease Inhibitor

Oral baloxavir marboxil is a Cap-dependent polymerase acidic endonuclease inhibitor that interferes with viral RNA transcription and blocks virus replication.[52] It is approved for use within 48 hours of illness onset, in people aged 12 years and older, for the treatment of acute, uncomplicated influenza in patients who are at high risk for developing serious influenza-related complications, for example, those with chronic conditions like asthma, heart disease, and diabetes. Avoid co-administration of baloxavir with dairy products, calcium-fortified beverages, polyvalent cation-containing laxatives or antacids, or oral supplements (eg, calcium, iron, magnesium, selenium, or zinc).[52] When administered within 48 hours of symptom onset, baloxavir decreased duration of illness by 2.5 days. The safety and efficacy of baloxavir in patients less than 12 years of age or weighing less than 40 kg have not been established. Baloxavir is not recommended for use in pregnant women or breastfeeding mothers. Commonly reported events for baloxavir were diarrhea, bronchitis, nausea, nasopharyngitis, and increased liver enzymes.[52] The recommended doses are listed in Table 131-4.

Neuraminidase Inhibitors

⑨ ⑩ Oseltamivir, zanamivir, and peramivir are NA inhibitors that have activity against both influenza A and influenza B viruses.[51] Without NA, release of the virus from infected cells is impaired, and, thus, viral replication is decreased. Although no randomized, placebo-controlled trials of antiviral treatment have been conducted in hospitalized influenza patients to establish the efficacy of NA inhibitors, a number of observational studies have reported clinical benefits of NA inhibitors in hospitalized patients, including reduction in duration of hospitalization and risk of death, including ICU patients.[62,63] When administered within 48 hours of the onset of illness, NA inhibitors may reduce the duration of illness by approximately 1 day versus placebo. Neuroaminidase inhibitors shortened symptom duration in adults by 0.5 to 1 day, and improved survival in hospitalized patients.[63] In children, NA inhibitor use resulted in shorter duration of illness and 34% lower risk of otitis media.[64] Treatment of children with laboratory-confirmed influenza with oseltamivir significantly reduced the duration of illness by 17.6 hours[64] This has a significant effect on not only the quality of life for the patient but also the societal costs associated with influenza. The benefits of treatment are highly dependent on the timing of the initiation of treatment, with the ideal initiation period being within 12 hours of illness onset, up to 48 hours after onset of illness.[35,36,51] Debate still exists regarding the benefit of antiviral administration more than 48 hours after onset. Observational studies have reported a lower risk for severe outcomes with oral oseltamivir started as late as 4 and 5 days after onset of illness in critically ill patients with suspected or confirmed influenza.[65–67] Based upon the available observational data in hospitalized patients with influenza, including ICU patients, initiation of NA inhibitor treatment is recommended as soon as possible for hospitalized patients with suspected or confirmed influenza.

Oseltamivir treatment in adults and adolescents with documented influenza illness resulted in a 27% reduction in overall antibiotic use, a 55% reduction in lower respiratory tract complications (bronchitis, pneumonia), and a 59% reduction in hospitalizations.[68] Zanamivir treatment in adults and adolescents with influenza-like illness resulted in a 28% reduction in antibiotic use and a 40% reduction in lower respiratory tract complications.[69] The data in these studies largely come from healthy individuals rather than those at highest risk for complications associated with influenza. The impact of appropriate treatment in high-risk populations may be even greater than that documented to date.

Oseltamivir is FDA approved for treatment in those aged 14 days and older, zanamivir for treatment in those older than 7 years, and peramivir for those aged 2 years and older.[51] The CDC, the American Academy of Pediatrics (AAP), and the Pediatric Infectious Diseases Society (PIDS) provide an expanded recommendation for oseltamivir for treatment of infants younger than 14 days.[35,51] The recommended doses vary by agent and age (see Table 131-4). The recommended duration of treatment for both oseltamivir and zanamivir is 5 days, and one dose for 1 day for peramivir.

The FDA approved single-dose peramivir injection (Rapivab®) for intravenous use for the treatment of acute uncomplicated influenza in people aged 2 years and older.[36,51] Peramivir is as effective as oseltamivir, without severe adverse events.[70,71] It is an effective option in patients who are unable to tolerate or absorb oral or enterically administered oseltamivir due to gastric stasis, malabsorption, or gastrointestinal bleeding. Enteric oseltamivir and intravenous peramivir had similar clinical benefits in hospitalized influenza patients.[70] The benefit of peramivir beyond 1 day has not been demonstrated. Intravenous peramivir at a dosage of 600 mg once daily (10 mg/kg once daily in children) for 5 days plus standard of care did not demonstrate a clinical benefit compared with placebo plus standard of care in hospitalized patients younger than 6 years.[72]

Neuropsychiatric complications consisting of delirium, seizures, hallucinations, and self-injury in pediatric patients (mostly from Japan) have been reported following treatment with oseltamivir, and peramivir. Since influenza itself can be associated with neuropsychiatric manifestations, a causal relationship between oseltamivir or peramivir and neuropsychiatric effects has not been delineated. However, the labels for oseltamivir and peramivir have been updated to include neuropsychiatric events as a precaution, and their occurrence with use of these agents should not be ignored.

Influenza resistance to the NA inhibitors has been documented but cross-resistance between the NA inhibitors has not.[21,51] Antiviral resistance remains relatively low. During the 2018 to 2019 influenza season, 99% of the tested A(H1N1) pdm09 viruses were susceptible to oseltamivir and peramivir, and 100% of the 2009 H1N1 viruses tested were susceptible to zanamivir; 100% of influenza A (H3N2) tested were susceptible to both oseltamivir and zanamivir; and 100% of influenza B viruses tested were susceptible to both oseltamivir and zanamivir.[21,51] Antiviral susceptibility testing of circulating viruses confirmed that seasonal influenza A H3N2 and variant influenza H3N2 maintain susceptibility to oseltamivir, peramivir, and zanamivir.[21] The burden of surveillance rests on clinicians to identify local patterns of influenza circulation to guide antiviral therapy.

Special Populations

There is inadequate data for the use of anti-influenza medications in special populations, such as immunocompromised hosts. Furthermore, there is limited data for use of influenza antivirals during pregnancy. The adamantanes are embryotoxic and teratogenic in rats, and limited case reports of adverse fetal outcomes following amantadine use in humans have been published. Oseltamivir and zanamivir have been used but lack solid safety clinical data in pregnant females. Pregnancy should not be considered a contraindication to oseltamivir or zanamivir use. Oseltamivir is preferred for the treatment of pregnant females because of its systemic activity; however, the drug of choice for chemoprophylaxis is not yet defined. Zanamivir may be preferred because of its limited systemic absorption, but respiratory complications need to be considered, especially in females with underlying respiratory diseases. Both the adamantanes and the NA inhibitors are excreted in breast milk and should be avoided by mothers who are breastfeeding their infants. More studies are needed in these populations who are at high risk for serious disease and complications from influenza.

PANDEMIC PREPAREDNESS

This chapter is not meant to provide an exhaustive review of the biology of influenza or pandemic preparedness. This topic is rapidly changing and interested readers are referred to the following Websites: *www.flu.gov*, *www.who.int/influenza/human_animal_interface/en/*, and *www.cdc.gov/h1n1flu*.

A vital component of pandemic preparedness is forethought—plans must be established for how to effectively triage large numbers of ill patients, prioritize and/or ration vaccine and antivirals, and communicate with the public through mass media during a period of severe labor shortage (a result of stress and illness among healthcare workers) and supply shortfall (a result of societal and economic disruption).

EVALUATION OF THERAPEUTIC OUTCOMES

Patients should be monitored daily for resolution of signs and symptoms associated with influenza, such as fever, myalgia, headache, malaise, nonproductive cough, sore throat, and rhinitis. These signs and symptoms will typically resolve within approximately 1 week. If the patient continues to exhibit signs and symptoms of illness beyond 10 days or a worsening of symptoms after 7 days, a physician visit is warranted as this may be an indication of a secondary bacterial infection. Ideally, antiviral therapy should not be started until influenza is confirmed via the laboratory. However, therapy should be initiated within 48 hours of illness onset, emphasizing the need for rapid diagnosis. Repeat diagnostic tests to demonstrate clearance of the virus are not necessary.

SELF-ASSESSMENT QUESTIONS

1. A 21-year-old, otherwise healthy, female college student presents to clinic with history of 4 days of fever, myalgia, dry cough, and malaise. She is diagnosed with influenza A infection. What would be the most appropriate recommendation for her?

    A. Oseltamivir 75 mg once daily for 5 days

    B. Maintenance of fluid intake, warm tea, and cough lozenges

    C. Oseltamivir 75 mg plus rimantadine 100 mg twice daily for 5 days

    D. Zanamivir 10 mg twice daily for 5 days plus maintenance of fluid intake, warm tea, and cough lozenges

2. Which of the following characteristics is *true* for the influenza B virus?

    A. Responsible for the seasonal epidemics of influenza

    B. Typically associated with sporadic outbreaks

    C. Categorized into subtypes based on hemagglutinin and neuraminidase

    D. Does not cause disease in humans

3. Which of the following statements is *true* regarding antigenic drift and antigenic shift?

    A. Antigenic shift occurs when point mutations in the surface antigens of a particular subtype create antigenic variants, resulting in small changes in the hemagglutinin and/or neuraminidase molecules.

    B. Antigenic drift occurs when the influenza virus acquires a new hemagglutinin and/or neuraminidase via genetic reassortment.

    C. Antigenic shift causes seasonal epidemics of influenza and is the rationale behind the recommendation for annual vaccination.

    D. Antigenic drift causes seasonal epidemics of influenza and is the rationale behind the recommendation for annual vaccination.

4. What elements are needed for an avian influenza pandemic to occur?

    A. Sustained transmission from human to human

    B. Direct transmission from bird to human

    C. An influenza virus against which humans have no immunity

    D. All of the above

5. The influenza virus can be transmitted person-to-person via which of the following mechanisms?

   A. Influenza virus is not transmitted person-to-person.

   B. Via inhalation of respiratory droplets after someone sneezes

   C. Contact with an object contaminated with respiratory secretions, such as a used tissue

   D. Both B and C could allow viral transmission.

6. How long after the onset of illness are children considered infectious?

   A. 2 days

   B. 5 days

   C. 7 days

   D. ≥10 days

7. Which of the following patients should not receive the live-attenuated influenza vaccine (LAIV)?

   A. A 45-year-old male hemodialysis patient

   B. A healthy 2-year-old girl

   C. A 37-year-old female with HIV and a CD4 cell count of 150 cells/mm^3 (0.15 × 10^9/L)

   D. A healthy 39-year-old accountant

8. A 52-year-old female presents with fever, malaise, nonproductive cough, and sore throat for the last 5 days. She is diagnosed with influenza. What other signs and symptoms of influenza would be classical for this patient?

   A. Rhinitis

   B. Nausea and vomiting

   C. Otitis media

   D. None of the above is classical signs and symptoms of influenza.

9. Which diagnostic test would be the *most* appropriate to use in the patient from #8 to provide a rapid result?

   A. Rapid antigen test

   B. Direct fluorescence antibody test

   C. Viral culture

   D. All of the above could be used in this patient for rapid diagnosis.

10. In which of the following patients would prophylaxis with an antiviral medication be appropriate?

   A. A vaccinated (received 1 month ago) 74-year-old male resident of a long-term care facility with a current influenza outbreak

   B. A 54-year-old female presenting to clinic to receive her influenza vaccination because she heard about several influenza cases in the community

   C. An unvaccinated 34-year-old mother of three (healthy children aged 3, 6, and 9 years)

D. Prophylaxis with antiviral medication is appropriate in all of the above.

11. Which of the following is the most appropriate prophylactic regimen for the patient(s) requiring prophylaxis from #10?

    A. Rimantadine 200 mg once daily for the duration of influenza activity

    B. Zanamivir 10 mg twice daily for 5 days

    C. Oseltamivir 75 mg daily for up to a week after last documented influenza infection

    D. Zanamivir 10 mg twice daily for 2 days

12. Which of the following statements is *true*?

    A. Thimerosal-free vaccines are available because thimerosal causes autism.

    B. No thimerosal-free formulations of the influenza vaccine are available.

    C. No scientifically persuasive evidence exists to suggest harm from thimerosal exposure from a vaccine.

    D. The risks of using a thimerosal-containing vaccine outweigh the benefits of receiving the influenza vaccine.

13. Which of the following patients is *not* at high risk for complications or severe disease from seasonal influenza infection?

    A. A 28-year-old pregnant woman at 34 weeks' gestation with no significant medical history

    B. A 47-year-old male with hypertension successfully managed with lisinopril

    C. An 82-year-old female residing in a nursing home

    D. A 12-year-old boy with asthma

14. Adamantane monotherapy would be most appropriate in which of the following situations?

    A. Prophylaxis for patients in a nursing home during an influenza A outbreak

    B. Prophylaxis for patients in a nursing home during an influenza B outbreak

    C. Treatment in a 58-year-old male presenting within 36 hours of the onset of illness

    D. Use of the adamantanes is not appropriate for monotherapy because of rapid development of resistance

15. What are the primary subtypes of influenza A that have been circulating among humans over the past 30 years?

    A. H3N2 and H1N1v

    B. H3N2 and H5N1

    C. H3N2 and H1N1

    D. H2N2 and H5N1

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** Antiviral if used, should be started within 48 hours of symptom onset to maximize effectiveness. This patient is presenting with 4 days history of fever, etc. A is incorrect, because oseltamivir dose is incorrect for treatment and patient presenting outside the recommended treatment window. C is incorrect because rimantadine is no longer recommended for treatment or prophylaxis of influenza A. Although oseltamivir dose is correct, it is

unknown of the benefit since it has been 4 days since symptom onset. Likewise, D is incorrect – symptom is greater than 48 hours onset.

2. **B.** B is correct as influenza B viruses are typically associated with sporadic outbreaks, particularly among residents of long-term care facilities. A is incorrect as that is the characteristics of influenza A as we have seen various variants with antigenic drift over the years. C is a characteristic of influenza A. Influenza B viruses do not have subtypes. D is incorrect, influenza B causes disease in humans and is included in seasonal influenza vaccine.

3. **D.** Seasonal influenza epidemics are the result of viral antigenic drift, which is why the influenza vaccine is changed on a yearly basis. Antigenic drift forms the foundation of the recommendation for annual influenza vaccination. The acquisition of a new hemagglutinin and/or neuraminidase by the influenza virus is called antigenic shift, which results in a novel influenza virus that has the potential to cause a pandemic. A and B are incorrect as they do not describe Antigenic shift or Antigenic drift. C is incorrect – antigenic shift is the basis for pandemic when influenza A acquires hemagglutinin and/or neuraminidase leading to a novel virus. D is correct and describes antigenic drift phenomenon. See Key Concepts 2 and 3.

4. **D.** These are novel viruses that must be able to replicate in humans, spread person-to-person, and affect a susceptible population. The spread of avian influenza viruses from person-to-person is rare, and has been limited, inefficient, and unsustained. Therefore A, B, C all have to be present for a pandemic. D is the correct answer. See the Avian Iinfluenza section and Key Concept 3.

5. **D.** A is incorrect because the spread of influenza is person-to-person. B and C are correct modes of transmission. Therefore, D is the correct answer.

6. **D.** Children, especially younger children, might potentially be infectious for longer periods (more than 10 days). Therefore A, B, C are incorrect. See the Influenza Pathogenesis section.

7. **C.** LAIV4 is FDA approved for adults younger than 49 years. LAIV4 should not be used during pregnancy. LAIV should not be given to immunosuppressed patients or given by healthcare workers who are severely immunocompromised. LAIV should not be administered to persons with a history of GBS or hypersensitivity to eggs. The ACIP recommends that anyone with a severe allergic reaction (eg, anaphylaxis) to any egg-based IIV or LAIV of any valency should receive non-egg-based influenza vaccine. A is incorrect because is a candidate for vaccine. B and D are candidates for LAIV vaccine. C is immunocompromised AIDS patient and should not receive LAIV vaccine due to theoretical infection risk. The patient also has hypersensitivity to eggs, although types and severity are unknown. See Table 131-3.

8. **A.** Classic signs and symptoms include abrupt onset of fever, muscle pain, headache, malaise, nonproductive cough, sore throat, and rhinitis. These are also symptoms to monitor for resolution of illness. A is correct, rhinitis is one of the cardinal symptoms. B and C are incorrect as they are not classic signs or symptoms. See Key Concept 5.

9. **B.** Rapid antigen test provides results within 10 to 15 minutes; however, do not provide any information about influenza A virus subtypes. Sensitivities for rapid antigen test range are low often yielding false-negative results. Rapid antigen test is not recommended for use in hospitalized patients with suspected influenza, and are not preferred in outpatient settings. Therefore, A is incorrect. C is incorrect because it does not yield timely results to inform clinical management. Shell-vial tissue culture results may take 1 to 3 days, while traditional tissue-cell viral culture results may take 3 to 10 days. D is incorrect because B is an appropriate test. B is correct and yields result in 1 to 4 hours. Immunofluorescence assays (IFAs) have moderate sensitivity and high specificity. See laboratory tests.

10. **A.** A is correct, because meets definition of high risk (age and chronic care facility) where there is an outbreak. B is incorrect, as this is a healthy individual who is not considered high risk. C is incorrect because although unvaccinated is not considered high risk. D is incorrect because B and C are incorrect. For discussion on who is high risk for complication or severe influenza illness. Prophylaxis for seasonal influenza should be considered during influenza season for the following groups of patients after exposure to an infectious source:

    1. Persons at high risk of serious illness and/or complications who are exposed to an infectious person and cannot be vaccinated.

    2. Persons at high risk of serious illness and/or complications who are vaccinated but exposed to an infectious person during the first 2 weeks following vaccination. The development of sufficient antibody titers after vaccination takes approximately 2 weeks.

    3. Persons with severe immune deficiency or who may have an inadequate response to vaccination (eg, advanced human immunodeficiency virus [HIV] disease, persons receiving immunosuppressive medications), after exposure to an infectious person.

4. Long-term care facility residents, regardless of vaccination status, when an outbreak has occurred in the institution.

11. **C.** A is incorrect because it is an amantadine which are no longer effective. B is incorrect because dose and duration of zanamivir corresponds to treatment of influenza. D is incorrect because duration of prophylaxis therapy of 2 days and frequency of dosing is also incorrect for prophylaxis. Dosing frequency for prophylaxis is daily. C is correct – dose and frequency of dosing are appropriate and since this is an outbreak at chronic care facility, prophylaxis should be continued beyond 10 days until last documented influenza infection. See Table 131-4 for drug dosing.

12. **C.** A is incorrect because, although thimerosal-free vaccines are available but not because thimerosal causes autism. B is incorrect because thimerosal-free vaccines are available. C is correct as no evidence has causal effect of thimerosal and autism. D is incorrect because the preventive benefit of influenza vaccine outweigh any unfounded risk of autism from thimerosal in influenza vaccine. See text on thimerosal discussion.

13. **B.** People who are at high risk of serious complications from influenza, including H3N2v virus infection, are: children younger than 5 years, people older than or equal to 65 years, pregnant women, body mass index of 40 or higher, age less than 19 years of age on long-term aspirin or salicylate containing drugs, chronic care facility residents, and people with certain chronic medical conditions (asthma, cystic fibrosis, chronic obstructive pulmonary disease, diabetes, heart disease, stroke, sickle cell, kidney and liver disorders, inherited metabolic disorders, immunocompromised, and neurologic or neurodevelopmental conditions). A is correct because pregnancy considered high risk. C is correct because elderly (>65 years) and resides in nursing home (chronic care facility resident). D is correct due to presence of chronic medical condition, asthma. B is incorrect, age 47 and hypertension do not qualify as high risk for influenza qualification. See text on patients at high risk for complications or severe disease.

14. **D.** A, B, C are incorrect because adamantanes show >99% ineffectiveness against influenza A H1N1. Adamantanes do not have activity against influenza A H3N2 or influenza B viruses. Therefore, they may not be used for prophylaxis or treatment.

15. **C.** The correct answer is C. These influenza A subtypes and influenza B are the main targets for yearly influenza vaccine. A is incorrect since there is not a H1N1 variant in circulation. There is H3N2 variants. B and D are incorrect because H5N1 and H2N2 are not predominantly in circulation. H5N1 is Avian influenza and H2N2 is Asian influenza.

Chapter 133: Skin and Soft Tissue Infections

Douglas N. Fish

KEY CONCEPTS

KEY CONCEPTS

① Folliculitis, furuncles (boils), and carbuncles begin around hair follicles and are caused most often by *Staphylococcus aureus*. Folliculitis and small furuncles are generally treated with warm, moist heat to promote drainage; larger furuncles and carbuncles require incision and drainage. Purulent, moderately severe infections (eg, with fever or other systemic signs of infection) have a higher suspicion for community-associated methicillin-resistant *S. aureus* (MRSA) and empiric treatment should include trimethoprim–sulfamethoxazole or a tetracycline such as doxycycline.

② Erysipelas, a superficial skin infection with extensive lymphatic involvement, is caused by *Streptococcus pyogenes*. The treatment of choice is penicillin, administered orally or parenterally, depending on the severity of the infection.

③ Impetigo is a superficial skin infection that occurs most commonly in children. It is characterized by fluid-filled vesicles that rapidly develop into pus-filled blisters that rupture to form golden-yellow crusts. Effective therapy includes penicillinase-resistant penicillins (dicloxacillin), first-generation cephalosporins (cephalexin), and topical mupirocin or retapamulin. *S. aureus* is the primary cause of impetigo, with MRSA becoming more common in recent years.

④ Lymphangitis, an infection of the subcutaneous lymphatic channels, is usually caused by *S. pyogenes*. Acute lymphangitis is characterized by the rapid development of fine, red, linear streaks extending from the initial infection site toward the regional lymph nodes, which are usually enlarged and tender. Penicillin is the drug of choice.

⑤ Cellulitis is an infection of the epidermis, dermis, and superficial fascia most commonly caused by *S. pyogenes* and *S. aureus*. Lesions generally are hot, painful, and erythematous, with nonelevated, poorly defined margins. Oral trimethoprim–sulfamethoxazole, doxycycline, or minocycline is used for initial treatment of suspected MRSA in patients with purulent, moderately severe cellulitis (ie, lesion with purulent drainage or exudate, or nondrainable abscess plus systemic signs of infection). Treatment of nonpurulent cellulitis generally consists of penicillin VK, a penicillinase-resistant penicillin (dicloxacillin), first-generation cephalosporin (cephalexin), or clindamycin for 5 days, coverage for MRSA may be added in certain patients. More severe infections in hospitalized and/or immunocompromised patients should receive empiric therapy with parenteral agents active against streptococci (nonpurulent infections) or both streptococci and MRSA (purulent infections).

⑥ Necrotizing fasciitis is an uncommon but life-threatening infection of subcutaneous tissue that results in progressive destruction of superficial fascia and subcutaneous fat. Early and aggressive surgical debridement is an essential part of therapy for treatment of necrotizing fasciitis. Mixed infections are treated with broad-spectrum regimens that cover streptococci, gram-negative aerobes, and anaerobes. Infections caused by *S. pyogenes* or *Clostridium* species should be treated with the combination of penicillin and clindamycin.

⑦ Diabetic foot infections are managed with a comprehensive treatment approach that includes both proper wound care and antimicrobial therapy. Potential pathogens include staphylococci, streptococci, aerobic gram-negative bacilli, and obligate anaerobes. Antimicrobial regimens for diabetic foot infections are based on severity of the infection, expected treatment setting, and risk factors for infection with more resistant pathogens such as MRSA and *Pseudomonas aeruginosa*. Outpatient therapy with oral antimicrobials should be used whenever possible for less severe infections, while more severe infections initially require IV therapy.

⑧ Prevention is the single most important aspect in the management of pressure injuries. After an injury develops, successful local care includes a comprehensive approach consisting of relief of pressure, proper cleaning (debridement), disinfection, and appropriate antimicrobial therapy if an infection is present. Good wound care is crucial to successful management.

⑨ All bite wounds (animal or human) should be thoroughly irrigated with large volumes of sterile normal saline, and the injured area should be immobilized and elevated. Depending on the severity of the bite wound, amoxicillin–clavulanic acid or ampicillin–sulbactam is often used for treatment of animal bites because of their coverage of *Pasteurella* species, streptococci, *S. aureus*, and anaerobes typically present in the oral flora of dogs and cats.

⑩ Antimicrobial prophylaxis (early preemptive therapy) of animal bites is not routinely recommended; however, patients at high risk of infection (eg, immunocompromised, moderate-to-severe bite injuries especially to the hands and face, penetration of the periosteum or joint capsule) should be given prophylactic antimicrobial therapy for 3 to 5 days. Infected bite wounds should be treated for 7 to 14 days with oral or IV antibiotics having activity against *Eikenella corrodens*, streptococci, *S. aureus*, and β-lactamase–producing anaerobes.

BEYOND THE BOOK

BEYOND THE BOOK

Refer to "Chapter 126: Skin and Soft Tissue Infection: A Pain in the Butt Level II" in Pharmacotherapy Casebook: A Patient-Focused Approach, 11e (may be obtained online through AccessPharmacy). After studying the patient presentation, briefly answer Questions 1 through 5 and the Follow-Up Case Questions 1 through 9 regarding patient Jimmie Chipwood's skin and soft tissue infection (SSTI). The purpose of this exercise is to gain experience in applying knowledge regarding SSTI to assess infections in individual patients and develop an appropriate therapeutic plan based on clinical presentation, type and severity of infection, past treatment history, potential causative pathogens, and patient characteristics

INTRODUCTION

Skin and soft-tissue infections (SSTIs) may involve any or all layers of the skin (epidermis, dermis, subcutaneous fat), fascia, and muscle. They may also spread far from the initial site of infection and lead to more severe complications, such as endocarditis, gram-negative sepsis, or streptococcal glomerulonephritis. Sometimes the treatment of SSTIs may necessitate both medical and surgical management. This chapter presents details of the pathogenesis and management of some of the most common infections involving the skin and soft tissues, ranging in severity from superficial to life-threatening.

EPIDEMIOLOGY

Bacterial infections of the skin can be classified as primary or secondary (Table 133-1).[1–4] Primary bacterial infections usually involve areas of previously healthy skin and are caused by a single pathogen. In contrast, secondary infections occur in areas of previously damaged skin and are frequently polymicrobic. SSTIs are also classified as complicated or uncomplicated. Complicated infections are those that involve deeper skin structures (eg, fascia, muscle layers), require significant surgical intervention, and/or occur in patients with compromised immune function (eg, diabetes mellitus, human immunodeficiency virus [HIV] infection).[3–5] Other categories that are crucial for successful treatment are the differentiation of necrotizing versus non-necrotizing, as well as purulent versus nonpurulent, SSTIs.[3–6] Acute bacterial skin and skin structure infections (ABSSSIs) are a subset of SSTI and specifically denote those more severe bacterial infections of the skin with a lesion size area of at least 75 cm^2 and for which antibiotic therapy is generally considered to be required for successful resolution.[7] The subset of ABSSSI specifically includes cellulitis, erysipelas, wound infection, and major cutaneous abscess.[7]

TABLE 133-1

Bacterial Classification of Important Skin and Soft-Tissue Infections

Primary Infections	
Erysipelas	Group A streptococci (*Streptococcus pyogenes*)
Impetigo	*Staphylococcus aureus* (including methicillin-resistant strains), group A streptococci
Lymphangitis	Group A streptococci; occasionally *S. aureus*
Cellulitis	Group A streptococci, *S. aureus* (potentially including methicillin-resistant strains); occasionally other gram-positive cocci, gram-negative bacilli, and/or anaerobes
Necrotizing fasciitis	
Type I	Anaerobes (*Bacteroides* spp., *Peptostreptococcus* spp.) and facultative bacteria (streptococci, Enterobacterales)
Type II	Group A streptococci
Type III	*Clostridioides perfringens*
Secondary Infections	
Diabetic foot infections	*S. aureus*, streptococci, Enterobacteriaceae, *Bacteroides* spp., *Peptostreptococcus* spp., *Pseudomonas aeruginosa*
Pressure sores	*S. aureus* including methicillin-resistant strains, streptococci, Enterobacterales, *Bacteroides* spp., *Peptostreptococcus* spp., *P. aeruginosa*
Bite wounds	
Animal	*Pasteurella* spp., *S. aureus*, streptococci, *Bacteroides* spp.
Human	*Eikenella corrodens*, *S. aureus*, streptococci, *Corynebacterium* spp., *Bacteroides* spp., *Peptostreptococcus* spp.
Burn wounds	*P. aeruginosa*, Enterobacterales, *S. aureus*, streptococci

Data from References 1,2,8.

SSTIs are among the most common infections seen in community and hospital settings.[9,10] However, most infections are mild and are treated in an outpatient setting, making it difficult to accurately quantify community-acquired SSTIs. SSTIs occur in approximately 14 million persons each year, being more common among those 50 years of age and older.[8,9,10] Emergency room visits for SSTIs continue to increase each year, attributed primarily to an increase in community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA) cellulitis and abscesses.[3–5,11] Both inpatient admissions and outpatient office visits due to SSTIs increased by approximately 65% over a nine-year period in the early 2000s; during this same period the prevalence of MRSA among SSTIs increased from 29% to 64% in one emergency department.[10,12] AIn 2011 SSTIs were responsible for over

750,000 hospitalizations and represented approximately 2% of all admissions.[10] Additionally, the frequency of infections caused by drug-resistant gram-positive cocci (particularly *S. aureus*) has been increasing.[3–6,10,11] While the high incidence of healthcare-associated MRSA (HA-MRSA) has been a major concern for many years, the emergence of CA-MRSA is even more problematic.[3–6,13–20] CA-MRSA are characteristically isolated from patients lacking typical risk factors (eg, prior hospitalization, long-term care facility residence) and are often susceptible to antibiotics such as trimethoprim–sulfamethoxazole, doxycycline, and clindamycin.[13–20] They also differ genetically from HA-MRSA with methicillin resistance carried on the type IV or V staphylococcal chromosomal cassette *mec* (SCC*mec*) element of the *mecA* gene.[1,13,18] CA-MRSA strains often harbor genes for Panton-Valentine leukocidin (PVL), a cytotoxin causing leukocyte destruction and tissue necrosis. In contrast, HA-MRSA strains usually lack genes for PVL and are associated with SCC*mec* alleles I to III.[1,13,15,18] While the incidence of HA-MRSA has declined in recent years,[21] the incidence of CA-MRSA has dramatically increased; nearly half (46%) of all culture-positive SSTIs are caused by MRSA and nearly 50% of all CA-MRSA are isolated from SSTIs.[3–6,9,10,20] Clinicians should suspect CA-MRSA in geographic areas with a high prevalence of these strains, or in recurrent or persistent infections that are not responding to appropriate β-lactam therapy. In addition to the emergence of CA-MRSA, there is also concern about the use of clindamycin for CA-MRSA infections due to the risk of inducible clindamycin resistance in strains that are erythromycin-resistant, but clindamycin-susceptible.[8,15,18,21,23] A double-disk test (D-zone test) is recommended to identify erythromycin-resistant strains with inducible clindamycin resistance if treatment with clindamycin is desired.[4,6,13,15,18,24] A positive D-zone test, indicating the presence of inducible resistance conferred by the *erm* gene, suggests the possibility of the emergence of clindamycin resistance during therapy.[13,15,18,24]

ETIOLOGY

The majority of SSTIs are caused by gram-positive organisms present on the skin surface.[2,6,22] Gram-positive bacteria (coagulase-negative staphylococci, diphtheroids) are the predominant flora of healthy skin, with gram-negative organisms being relatively uncommon (Table 133-2).[1,2,8,22] *S. aureus*, as well as a variety of gram-negative bacteria, including *Acinetobacter* species, can be found in moist intertriginous areas (eg, axilla, groin, and toe webs) of the body.[1,2,22,23] Approximately 30% to 35% of healthy individuals are reported to be colonized with *S. aureus* on the skin or in the anterior nares.[1,8,22] Colonization, whether transient or permanent, provides a nidus for infection should the integrity of the epidermis be compromised.[1–3,5,6,8,22]

TABLE 133-2

Predominant Microorganisms of Normal Skin

Bacteria

- Gram-positive
  - Coagulase-negative staphylococci
  - Micrococci (*Micrococcus luteus*)
  - *Corynebacterium* species (diphtheroids)
  - *Propionibacterium* species
- Gram-negative
  - *Acinetobacter* species

Fungi

- *Malassezia* species
- *Candida* species

Data from References 1,2,8.

S. aureus and *S. pyogenes* account for the majority of community-acquired SSTIs.[1,12,15,22] Data from large surveillance studies showed *S. aureus* to be the most common cause of SSTIs in hospitalized patients, with often 30% to 50% of these being caused by MRSA.[8,10,12,13,17,20] Other common healthcare-associated pathogens included *Pseudomonas aeruginosa* (11%), enterococci (9%), and *Escherichia coli* (7%).[6,8,10,13]

PATHOPHYSIOLOGY

The skin serves as a barrier between humans and their environment, therefore functioning as a primary defense mechanism against infections. The skin and subcutaneous tissues normally are extremely resistant to infection but may become susceptible under certain conditions. Although the human skin supports an abundant and diverse microbiome of bacteria and fungi,[1,2,22] several host factors act together to confer protection against skin infections. Continuous renewal of the epidermal layer results in the shedding of keratocytes, as well as skin bacteria.[2,22] In addition, sebaceous secretions are hydrolyzed to form free fatty acids that strongly inhibit the growth of many bacteria and fungi. A normal commensal skin microbiome itself serves as a protective function by not allowing space or environmental conditions favorable to colonization with more pathogenic strains.[1,2,22] Conditions that may predispose a patient to the development of skin infections include (a) high concentrations of bacteria (more than 10^5 microorganisms), (b) excessive moisture of the skin, (c) inadequate blood supply, (d) availability of bacterial nutrients, and (e) damage to the corneal layer allowing for bacterial penetration.[2,3,5,8,22,23,25]

The best defense against SSTI is intact skin.[2,22,25] The majority of SSTIs result from the disruption of normal host defenses by processes such as skin puncture, abrasion, or underlying diseases (eg, diabetes).[1–3,5,8,22,25] The nature and severity of the infection depend on both the type of microorganism present and the site of inoculation.

FOLLICULITIS, FURUNCLES, AND CARBUNCLES

① Folliculitis is inflammation of the hair follicle and is caused by physical injury, chemical irritation, or infection. Infection occurring at the base of the eyelid is referred to as a stye. While folliculitis is a superficial infection with pus present only in the epidermis,[4,15,23] furuncles and carbuncles occur when a follicular infection around the hair shaft extends to involve deeper areas (subcutaneous tissue) of the skin.[4,15,23] A furuncle, commonly known as a *boil*, is a walled-off mass of purulent material arising from a hair follicle.[4,15,23] The lesions are called *carbuncles* when adjacent furuncles coalesce to form a single inflamed area.[4,15,23] This aggregate of infected hair follicles forms deep masses that generally open and drain through multiple sinus tracts.[15,23] *S. aureus* is the most common cause of folliculitis, furuncles, and carbuncles.[4,15,23] Outbreaks of furunculosis caused by *S. aureus* and CA-MRSA have been reported in settings involving close contact (eg, families, prisons), especially when skin injury was common (such as with athletes).[11] In addition, some individuals experience repeated episodes of furunculosis.[23] A major predisposing factor for recurrent infection is the presence of *S. aureus* in the anterior nares.[15,23]

CLINICAL PRESENTATION: Folliculitis, Furuncles, and Carbuncles

Folliculitis

- Clustering, pruritic papules localized to hair follicles.
- Generally develop in areas subject to friction and perspiration.
- Papules are generally 5 mm or less in diameter and erythematous.
- Papules evolve into pustules that generally spontaneously rupture in several days.
- Systemic signs (fever, malaise) are uncommon.

Furuncles

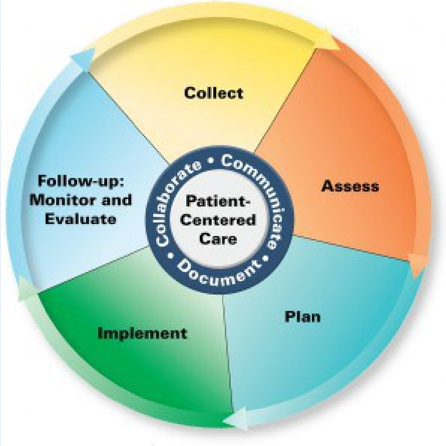
- Inflammatory, draining nodule involving a hair follicle.
- Develop in areas subject to friction and perspiration.
- Lesions are discrete, whether occurring as singular or multiple nodules.
- Lesion starts as a firm, tender, red nodule that becomes painful and fluctuant.
- Lesions often drain spontaneously.
- Lesions caused by CA-MRSA often have necrotic centers
- Systemic signs are uncommon.

Carbuncles

- Formed when adjacent furuncles coalesce to form a single inflamed area.
- Form broad, swollen, erythematous, deep, and painful follicular masses.
- Commonly develop on the back of the neck
- Commonly associated with systemic signs (fever, chills, malaise).
- Bacteremia with secondary spread to other tissues is common.

Patient Care Process

Patient Care Process for the Treatment of Skin and Soft-Tissue Infections (SSTIs)



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex, pregnant)
- Patient medical history
- Social history (eg, drug/ethanol use), animal exposures (if bite injury)
- Current and prior medications (eg, antimicrobials, immunosuppressive agents
- Objective data
    - Weight, temperature, blood pressure (BP), heart rate (HR), respiratory rate (RR), altered mental status (AMS), urine output (UO)
    - Laboratory findings including white blood cells (WBC) with differential, serum creatinine (SCr), liver function tests (LFT), blood glucose (especially for diabetic foot infection)
    - Culture and antimicrobial susceptibility data
    - Physical examination of skin lesions including location, size, appearance, presence of abscesses or ulcers, presence of purulence or drainage
    - Imaging studies (if suspicion for osteomyelitis, necrotizing fasciitis)

Assess

- Specific type of infection (see Clinical Presentation boxes for various SSTIs)
- Classification of infection severity, especially for cellulitis, diabetic foot infection, and pressure sores (see Tables 133-8 and 133-10)
- Risk for infection with specific pathogens (see Tables 133-1 and 133-9)
- Ability/willingness to be treated as outpatient, including potential adherence barriers
- Hemodynamic/clinical stability (eg, SBP <90 mmHg, HR >100 bpm, RR>22, AMS, decreased UO)
- Contraindications to specific antibiotic therapy (eg, age, allergies, drug–drug/disease interactions)

Plan*

- Antibiotic regimen including specific antimicrobial(s), dose, route, frequency, and duration (see Figs. 133-1–133-3; Tables 133-3–133-5 and 133-9)

- Monitoring parameters including efficacy (eg, improvement and/or healing of infectious lesions and other symptoms [depending on specific SSTI]), and safety (eg, antibiotic side effects, *Clostridioides difficile*); frequency and timing of follow-up
- Monitoring parameters for specific antibiotics administered to hospitalized patients (see Table 133-6)
- Patient education (eg, purpose of treatment, lifestyle modification, drug- and infection-specific information, medication administration)
- Self-monitoring for resolution of SSTI signs and symptoms, signs of worsening or unresponsive SSTI, when to seek additional medical attention
- Referrals to other providers when appropriate (eg, surgeon, diabetes educator, wound care specialist)

Implement*

- Provide patient and caregiver education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence to outpatient antibiotics
- Schedule follow-up as needed for more severe infections (eg, cellulitis, diabetic foot infection, pressure sores, bite wounds)

Follow-up: Monitor and Evaluate*

- Resolution of infectious symptoms (depending on specific type of SSTI)
- Presence of adverse effects specific to the antibiotic regimen
- Patient adherence to treatment plan using multiple sources of information
- Presence of drug-drug interactions potentially requiring changes in drug regimens or monitoring plans
- Therapeutic drug levels for specific agents used in hospitalized patients (see Table 133-6)

**Collaborate with patient, caregivers, and other healthcare professionals.*

Treatment: Folliculitis, Furuncles, and Carbuncles

Desired Outcomes

The goals of treatment include relieving discomfort, preventing further spread of the infection, and preventing recurrence. Controlling recurrent furunculosis is key due to the difficulty in treating chronic furunculosis. Treatments should be effective and inexpensive and have minimal adverse effects.

Pharmacologic Therapy

Table 133-3 summarizes evidence-based treatment recommendations from clinical guidelines for SSTIs.[3,4,8,15,26-28] Treatment of folliculitis generally requires only local measures, such as warm moist compresses or topical therapy (eg, clindamycin, erythromycin, mupirocin, retapamulin, or benzoyl peroxide).[8,23] Topical agents are typically applied two to four times daily for 7 days. Small furuncles generally can be treated with moist heat, which promotes localization and drainage of pus.[4,8,23] Large and/or multiple furuncles and carbuncles require incision and drainage.[4,5,8,13,15,23,27] Systemic antibiotics are usually not necessary unless accompanied by fever or extensive cellulitis.[4,5,15,23] Treatment of more severe infections (eg, accompanied by systemic signs of infection) should include oral trimethoprim–sulfamethoxazole or a tetracycline (doxycycline or minocycline) for 5 to 10 days due to a higher suspicion for MRSA (see Table 133-4 for adult and pediatric doses).[4,5,13,15,23,27] For individuals with nasal colonization, application of mupirocin ointment twice daily in the anterior nares for the first 5 days of each month decreases recurrent furunculosis by almost half.[13,15] Daily chlorhexidine washes and daily washing of personal items such as towels, bedding, and clothes may also be recommended.[15]

TABLE 133-3

Evidence-Based Recommendations for Treatment of Skin and Soft-Tissue Infections

Recommendations	Recommendation Grade[a]
Folliculitis, Furuncles, Carbuncles	
Gram stain and culture of pus from carbuncles and abscesses are recommended, but treatment without cultures is reasonable in most patients	Strong, moderate
Carbuncles, abscesses, and large furuncles of mild severity should be treated with incision and drainage	Strong, high
Administration of antibiotics with activity against *Staphylococcus aureus* as an adjunct to incision and drainage should be based on the presence or absence of systemic signs of infection	Strong, low
Antibiotics with activity against MRSA are recommended for patients with carbuncles or abscesses of higher severity who have failed initial antibiotic therapy, have severe systemic signs of infection, or are immunocompromised	Strong, low
Erysipelas	
Most infections are caused by *Streptococcus pyogenes*. Penicillin (oral or IV depending on clinical severity) is the drug of choice	A-I
If *S. aureus* is suspected, a penicillinase-resistant penicillin or first-generation cephalosporin should be used	A-I
Impetigo	
Gram stain and culture of pus or exudates should be obtained to help identify causative pathogens	Strong, moderate
Bullous and nonbullous impetigo should be treated with either mupirocin or retapamulin for 5 days	Strong, high
Impetigo should be treated with oral antibiotics active against *S. aureus* unless cultures show streptococci alone. Dicloxacillin or cephalexin is recommended for 7 days. Doxycycline, clindamycin, or sulfamethoxazole–trimethoprim should be used when MRSA is suspected or confirmed	Strong, moderate
Cellulitis	
Cultures of blood or cutaneous aspirates, biopsies, or swabs are not routinely recommended	Strong, moderate
Blood cultures are recommended, and cultures of cutaneous aspirates, biopsies, or swabs should be considered, in patients receiving chemotherapy for malignancies, neutropenia, severe cell-mediated immunodeficiency, immersion injuries, or animal bites	Strong, moderate (blood) Weak, moderate (other cultures)
Typical cases of mild nonpurulent cellulitis should be treated with antibiotics active against streptococci	Strong, moderate
Systemic antibiotics are recommended for moderate nonpurulent cellulitis with systemic signs of infection. Use of antibiotics active against methicillin-susceptible *S. aureus* could be considered	Weak, low
Patients with severe nonpurulent cellulitis associated with penetrating trauma, MRSA infection in another	Strong, moderate

location, MRSA nasal colonization, injection drug use, or systemic signs of infection should be treated with vancomycin or other antibiotics active against both MRSA and streptococci	
Broad-spectrum antibiotic therapy with vancomycin plus piperacillin–tazobactam, imipenem, or meropenem may be considered for empiric treatment of severe nonpurulent cellulitis in severely immunocompromised patients	Weak, moderate (need for broad-spectrum therapy), strong, moderate (recommended broad-spectrum antibiotic regimen if used)
A treatment duration of 5 days is recommended for cellulitis, but may be extended if lack of clinical response within that time	Strong, high
Elevation of the affected area and treatment of predisposing factors are recommended for cellulitis	Strong, moderate
Systemic corticosteroids for 7 days can be considered for adjunctive treatment of cellulitis in nondiabetic patients	Weak, moderate
Patients with mild nonpurulent cellulitis who do not have systemic signs of infection, altered mental status, or hemodynamic instability should be treated as outpatients	Strong, moderate
Hospitalization is recommended for patients with moderate-to-severe nonpurulent cellulitis who have failed outpatient therapy, have poor adherence to therapy, are immunocompromised, or in whom there is a concern for deeper or necrotizing infection	Strong, moderate
Empiric antibiotics for outpatients with purulent cellulitis should provide activity against community-associated MRSA; coverage of β-hemolytic streptococci is likely not required. Mild-to-moderate infections can generally be treated with oral agents (dicloxacillin, cephalexin, clindamycin) unless resistance is high in the community	A-II
Recommended antibiotics for empiric coverage of MRSA in outpatients include orally administered trimethoprim–sulfamethoxazole, doxycycline, minocycline, clindamycin, and linezolid	A-II for all listed options
If coverage of both β-hemolytic streptococci and community-associated MRSA is desired, empiric antibiotic regimens for outpatient therapy include orally administered clindamycin alone; linezolid alone; or trimethoprim–sulfamethoxazole, doxycycline, or minocycline in combination with amoxicillin	A-II for all listed options
Hospitalized patients with complicated or purulent cellulitis should receive IV antibiotics with activity against MRSA pending culture data. Antibiotic options include vancomycin, linezolid, daptomycin, telavancin, and clindamycin	A-I for all except clindamycin; clindamycin A-III
In patients with suspected or definitive serious MRSA infections, an individualizedtarget of the AUC/MIC ratio of 400 to 600 (assuming a vancomycin MIC of 1 mg/L) should be advocated to achieve clinical efficacy while improving patient safety	B-III
Necrotizing Fasciitis	
Patients with severe nonpurulent cellulitis characterized by aggressive infection and associated with signs of systemic toxicity, necrotizing fasciitis, or gas gangrene should have prompt surgical consultation	Strong, low
Early and aggressive surgical debridement of all necrotic tissue is essential	A-III
Necrotizing fasciitis should be empirically treated with broad-spectrum antibiotics such as vancomycin or	Strong, low

linezolid plus piperacillin–tazobactam or a carbapenem, or vancomycin or linezolid plus ceftriaxone and metronidazole	
Necrotizing fasciitis caused by *S. pyogenes* should be treated with the combination of clindamycin and penicillin	Strong, low
In the treatment of necrotizing fasciitis caused by methicillin-resistant *S. aureus* infections, trough serum vancomycin concentrations of 15-20 mg/L (10-14 μmol/L) are recommended	B-II
Clostridial gas gangrene (myonecrosis) should be treated with clindamycin and penicillin	A II
Diabetic Foot Infections	
Clinically uninfected wounds should not be treated with antibiotics	A-III
Empiric antibiotic regimens should be selected based on severity of infection and likely pathogens	A-III
Antibiotic therapy should target only aerobic gram-positive cocci in patients with mild-to-moderate infection who have not received antibiotics within the previous month	C-III
Broad-spectrum empiric antibiotic therapy should be initiated in most patients with severe infections, until culture and susceptibility data are available	A-III
Empiric antibiotics directed against *Pseudomonas aeruginosa* are usually unnecessary except in patients with specific risk factors for infection with this pathogen: patient has been soaking feet, patient has failed previous antibiotic therapy with nonpseudomonal agents, or clinically severe infection	A-III
Empiric antibiotics directed against MRSA should be considered in patients with specific risk factors, including prior history of infection or colonization with MRSA, high local prevalence of MRSA (eg, ≥50% for mild infections, ≥30% for severe infection), or clinically severe infection	C-III
Oral agents with high bioavailability may be used in the treatment of most mild, and many moderate, infections	A-II
Parenteral therapy is initially preferred for all severe, and some moderate, infections. After initial response, step-down therapy to oral agents can be considered	C-III
Definitive therapy should be based on results of appropriately collected cultures and sensitivities, as well as clinical response to empiric antimicrobial agents	A-III
Appropriate wound care, in addition to appropriate antimicrobial therapy, is often necessary for healing of infected wounds	A-III
Antibiotic therapy should only be continued until resolution of signs/symptoms of infection, but not necessarily until the wound is fully healed. The duration of therapy should initially be 1-2 weeks for mild infections and 2-3 weeks for moderate-to-severe infection	C-III
Pressure Ulcers	
Optimize the host response by evaluating nutritional status and addressing deficits; stabilizing glycemic control; improving arterial blood flow; and/or reducing immunosuppressant therapy if possible.	A-III

Consider the use of topical antiseptics for pressure ulcers that are not expected to heal and are critically colonized/topically infected.	B-III
Consider use of silver sulfadiazine in heavily contaminated or infected pressure ulcers until definitive debridement is accomplished.	B-III
Consider the use of medical-grade honey in heavily contaminated or infected pressure ulcers until definitive debridement is accomplished.	C-III
Limit the use of topical antibiotics on infected pressure ulcers, except in special situations where the benefit to the patient outweighs the risk of antibiotic side effects and resistance.	B-III
Use systemic antibiotics for individuals with clinical evidence of systemic infection, such as positive blood cultures, cellulitis, fasciitis, osteomyelitis, systemic inflammatory response syndrome (SIRS), or sepsis.	B-III
Animal Bites	
Preemptive early antibiotics should be administered for 3-5 days in patients with any of the following: immunocompromised; asplenic; advanced liver disease; preexisting or resultant edema of the bitten area; moderate-to-severe bite-related injuries, especially to the hands or face; or bite injuries that have penetrated the periosteum or joint capsule	Strong, low
Amoxicillin–clavulanic acid or other antibiotics active against both aerobic and anaerobic bacteria should be used for treatment of infected animal bites	Strong, moderate
Serious infections requiring IV antimicrobial therapy can be treated with a β-lactam/β-lactamase inhibitor combination or second-generation cephalosporin with activity against anaerobes (eg, cefoxitin)	B-II
Penicillinase-resistant penicillins, first-generation cephalosporins, macrolides, and clindamycin should not be used for treatment of infected wounds because of their poor activity against *Pasteurella multocida*	D-III
Human Bites	
Antimicrobial therapy should provide coverage against *Eikenella corrodens*, *S. aureus*, and β-lactamase–producing anaerobes	B-III

[a] Cited evidence-based guidelines utilize different systems for grading the strengths of recommendation and quality of the associated evidence. Qualitative (descriptive) recommendations are from Reference 15; letter- and roman numeral–based recommendations are from the other cited guidelines. Readers are advised to consult the original documents for full explanations of the grading systems and definitions used in individual guidelines.

Strength of recommendation: A, good evidence for use; B, moderate evidence for use; C, poor evidence for use, optional; D, moderate evidence to support not using; E, good evidence to support not using. *Quality of evidence*: I, evidence from ≥1 properly randomized controlled trials; II, evidence from ≥1 well-designed clinical trials without randomization, case–control analytic studies, multiple time series, or dramatic results from uncontrolled experiments; III, evidence from expert opinion, clinical experience, descriptive studies, or reports of expert committees.

Qualitative (descriptive) recommendations: *Strong, high*: strong recommendation, high-quality evidence from well-performed randomized controlled trials (RCTs) or exceptionally strong evidence from unbiased observational studies; *Strong, moderate*: strong recommendation, moderate quality evidence from RCTs with important limitations or exceptionally strong evidence from unbiased observational studies; *Strong, low*: strong recommendation, low-quality evidence for at least 1 critical outcome from observational studies, RCTs with serious flaws, or indirect evidence; *Weak, moderate*: weak recommendation, moderate quality evidence from RCTs with important limitations or exceptionally strong evidence from unbiased observational studies; *Weak, low*: weak recommendation, low-quality evidence for at least one critical outcome from observational studies, RCTs with serious flaws, or indirect evidence.

Data from References 3,4,8,15,26-29.

TABLE 133-4

Recommended Oral Drugs for Outpatient Treatment of Mild-to-Moderate Skin and Soft-Tissue Infections

Infection	Adults	Children
Folliculitis	None; warm saline compresses usually sufficient	
Furuncles and carbuncles	• Trimethoprim–sulfamethoxazole[a,b] • Doxycycline[a,b] Minocycline[a,b]	• Trimethoprim–sulfamethoxazole[a,b] • Clindamycin[a,b]
Erysipelas	• Procaine penicillin G • Penicillin VK • Clindamycin[a] • Erythromycin[a]	• Penicillin VK • Clindamycin[a] • Erythromycin[a]
Impetigo	• Mupirocin ointment[a] • Retapamulin ointment[a] • Dicloxacillin • Cephalexin • Trimethoprim–sulfamethoxazole[a,b] • Clindamycin[a,b] • Doxycycline[a,b]	• Mupirocin ointment[a] • Retapamulin ointment[a] • Dicloxacillin • Cephalexin • Trimethoprim–sulfamethoxazole[a,b] • Clindamycin[a,b]
Lymphangitis	• Initial IV therapy, followed by penicillin VK • Clindamycin[a]	• Initial IV therapy, followed by penicillin VK • Clindamycin[a]
Cellulitis	• Penicillin VK[c] • Cephalexin[c] • Dicloxacillin[c] • Clindamycin[b,c] • Trimethoprim–sulfamethoxazole[b,d] • Doxycycline[b,d] • Minocycline[b,d] • Linezolid[b]	• Penicillin VK[c] • Cephalexin[c] • Dicloxacillin[c] • Clindamycin[b,c] • Trimethoprim–sulfamethoxazole[b,d] • Linezolid[b]
Diabetic foot infections	• Dicloxacillin • Clindamycin • Cephalexin • Amoxicillin–clavulanate • Levofloxacin ± metronidazole or clindamycin[a,e]	

	- Ciprofloxacin ± metronidazole or clindamycin[a,e] - Moxifloxacin	
Bite wounds (animal or human)	- Amoxicillin–clavulanate - Doxycycline[a] - Moxifloxacin[a] - Trimethoprim–sulfamethoxazole + metronidazole or clindamycin[a] - Levofloxacin or ciprofloxacin + metronidazole or clindamycin[a] - Cefuroxime axetil + metronidazole or clindamycin - Dicloxacillin + penicillin VK	- Amoxicillin–clavulanate - Trimethoprim–sulfamethoxazole + metronidazole or clindamycin[a] - Cefuroxime axetil + metronidazole or clindamycin - Dicloxacillin + penicillin VK

[a] May be used in patients with penicillin allergy.

[b] Recommended if CA-MRSA is suspected.

[c] For nonpurulent cellulitis when CA-MRSA is not suspected, or purulent cellulitis when CA-MRSA not documented (not penicillin VK).

[d] May be combined with amoxicillin if additional coverage for streptococci is desired.

[e] Fluoroquinolone alone may be suitable for mild infections, while addition of drugs with antianaerobic activity may be recommended for more severe infections.

Evaluation of Therapeutic Outcomes

Many follicular infections resolve spontaneously without medical or surgical intervention. Lesions should be incised if they do not respond to a few days of moist heat and nonprescription topical agents. Following drainage, most lesions begin to heal within several days without antimicrobial therapy. Any patient who is unresponsive to several days of systemic antibiotic therapy or suffers recurrent infection should have a culture and sensitivity test performed to guide continued antibiotic selection.

ERYSIPELAS

② Erysipelas is a distinct form of cellulitis involving the more superficial layers of the skin and cutaneous lymphatics.[3,30,31] The intense red color and burning pain associated with erysipelas led to the common name of "St. Anthony's fire." The infection is almost always caused by β-hemolytic streptococci, with the organisms penetrating via small breaks in the skin. Group A streptococci (*S. pyogenes*) are responsible for most infections.[8,15,31] Infections are more common in infants, young children, older adults, and patients with nephrotic syndrome or who are immunocompromised.[4,8,30,31] Erysipelas also commonly occurs in areas of preexisting lymphatic obstruction or edema.[8,13,30,31] Diagnosis is made on the basis of the characteristic lesion.

CLINICAL PRESENTATION: Erysipelas

General

- Lower extremities are the most common sites.

Symptoms

- Flu-like symptoms (fever, chills, malaise) common prior to the appearance of the lesion.
- Infected area described as very painful or as a burning pain.

Signs

- Lesion is intensely erythematous and edematous, often with lymphatic streaking.
- Lesion has raised border, which is sharply demarcated from uninfected skin.
- Temperature is often mildly elevated.

Laboratory Tests

- Causative organism usually cannot be cultured from the skin surface.
- Needle aspiration or punch biopsies occasionally identify organism.
- Cultures considered for more severe cases (eg, atypical clinical findings such as fluid-filled blisters).

Other Diagnostic Tests

- Complete blood cell count is often performed, leukocytosis is common.
- C-reactive protein is also generally elevated.

Treatment: Erysipelas

Desired Outcomes

The goal of treatment of erysipelas is rapid eradication of the infection, thereby providing relief of symptoms (pain, tenderness, fever).[30] Preventing recurrent infection is also important as recurrence is a common complication, occurring in approximately 20% of patients.[30] Treatments should be effective and inexpensive, and have minimal adverse effects.

Pharmacologic Therapy

Mild-to-moderate cases of erysipelas are treated with intramuscular procaine penicillin G or oral penicillin VK for 7 to 10 days (see Table 133-4).[8,15,30] Recommended doses and monitoring parameters for selected antibiotics are given in Tables 133-5 and 133-6. Penicillin-allergic patients can be treated with clindamycin. For more serious infections, the patient should be hospitalized and administered IV aqueous penicillin G.[8,15] Marked improvement is seen within 48 hours, and the patient may be switched to oral penicillin to complete the course of therapy.

TABLE 133-5

Drug Dosing[a]

Drug	Brand Name	Usual Dosing Range	Special Population Dose	Other

Oral Agents				
Amoxicillin–clavulanate	Augmentin®	875/125 mg orally every 12 hours	Pediatric: 40 mg/kg (of the amoxicillin component) orally in two divided doses	
Cefaclor	Ceclor®	500 mg orally every 8 hours	Pediatric: 20-40 mg/kg/day (not to exceed 1 g) orally in three divided doses	
Cefadroxil	Duricef®	250-500 mg orally every 12 hours	Pediatric: 30 mg/kg orally in two divided doses	
Cefuroxime axetil	Ceftin®	250-500 mg orally every 12 hours	Pediatric: 20-30 mg/kg orally in two divided doses	
Cephalexin	Keflex®	250-500 mg orally every 6 hours	Pediatric: 25-50 mg/kg orally in four divided doses	
Ciprofloxacin	Cipro®	500-750 mg orally every 12 hours		
Clindamycin	Cleocin®	300-600 mg orally every 6-8 hours	Pediatric: 10-30 mg/kg/day orally in three to four divided doses[3]	May be used for oral treatment of MRSA infection
Delafloxacin	Baxdela®	450 mg orally every 12 hours		May be used for oral treatment of MRSA infection
Dicloxacillin	Dynapen®	250-500 mg orally every 6 hours	Pediatric: 25-50 mg/kg orally in four divided doses	
Doxycycline	Vibramycin®	100-200 mg orally every 12 hours		May be used for oral treatment of MRSA infection
Erythromycin	• E-Mycin® • Erythrocin®	250-500 mg orally every 6 hours	Pediatric: 30-50 mg/kg orally in four divided doses[a]	
Levofloxacin	Levaquin®	500-750 mg orally once daily		
Linezolid	Zyvox®	600 mg orally every 12 hours	Pediatric: 20-30 mg/kg/day orally in two to three divided doses	For oral treatment of MRSA infection
Metronidazole	Flagyl®	250-500 mg orally every 8 hours	Pediatric: 30 mg/kg orally in three to four divided doses	

Moxifloxacin	Avelox®	400 mg orally once daily		
Mupirocin ointment	Bactroban®	Apply to affected areas every 8 hours	Pediatric: apply to affected areas every 8 hours	
Penicillin VK	- Veetids® - Pen-V®	250-500 mg orally every 6 hours	Pediatric: 25,000-90,000 units/kg orally in four divided doses	
Retapamulin ointment	Altabax®	Apply to affected area every 12 hours	Pediatric: apply to affected area every 12 hours	
Tedizolid	Sivextro®	200 mg orally once daily		For oral treatment of MRSA infection
Trimethoprim–sulfamethoxazole	- Bactrim® - Septra® - Cotrimoxazole®	160/800 mg orally every 12 hours	Pediatric: 4-6 mg/kg (of the trimethoprim component) orally every 12 hours	Up to double the usual dose may be considered for oral treatment of MRSA infection
Parenteral Agents				
Ampicillin	- Omnipen® - Polycillin® - Principen®	1-2 g IV every 6 hours	Pediatric: 200-300 mg/kg/day IV in four to six divided doses	
Aztreonam	Azactam®	1 g IV every 6 hours	Pediatric: 100-150 mg/kg/day IV in four divided doses	
Cefazolin	- Ancef® - Kefzol®	1 g IV every 6-8 hours	Pediatric: 75 mg/kg/dayIV in three divided doses	
Cefepime	Maxipime®	1-2 g IV every 12 hours	Pediatric: 100 mg/kg/day IV in two divided doses	
Cefotaxime	Claforan®	1-2 g IV every 6 hours	150-200 mg/kg/day in three to four divided doses	
Cefoxitin	Mefoxin®	1-2 g IV every 6 hours	Pediatric: 30-40 mg/kg/day IV in four divided doses	
Ceftazidime	Fortaz®	1-2 g IV every 8 hours	Pediatric: 150 mg/kg/day IV in three divided doses	
Ceftaroline	Teflaro®	600 mg IV every 12 hours		For MRSA infection
Ceftriaxone	Rocephin®	1 g IV once daily		

Cefuroxime	Zinacef®	0.75-1.5 g IV every 8 hours	Pediatric: 150 mg/kg/day IV in three divided doses	
Ciprofloxacin	Cipro®	400 mg IV every 8-12 hours		
Clindamycin	Cleocin®	300-600 mg IV every 6-8 hours; 600-900 mg IV every 6-8 hours for necrotizing fasciitis	Pediatric: 30-50 mg/kg/day IV in three to four divided doses	
Dalbavancin	Dalvance®	1,000 mg IV once on Day 1 of therapy, followed by 500 mg IV once on Day 8 of therapy; OR 1,500 mg IV once with no additional doses	Pediatric: 22.5 mg/kg (less than 6 years of age) or 18 mg/kg/day (6-18 years of age) IV in one dose	For MRSA infection
Daptomycin	Cubicin®	4 mg/kg IV once daily		For MRSA infection
Delafloxacin	Baxdela®	300 mg IV every 12 hours		For MRSA infection
Doripenem	Doribax®	500 mg IV every 8 hours		
Ertapenem	Invanz®	1 g IV once daily	Pediatric: 30 mg/kg/day IV in one to two divided doses	
Gentamicin	Garamycin®	Traditional: 2 mg/kg loading dose, followed by 1.5 mg/kg IV every 8 hours and guided by measured serum concentrations. Alternative: 5-7 mg/kg IV once daily	Pediatric: 5-7 mg/kg/day IV in three divided doses; doses guided by serum concentrations	
Imipenem–cilastatin	Primaxin®	250-500 mg IV every 6-8 hours	Pediatric: 40-80 mg/kg/day IV in four divided doses	
Levofloxacin	Levaquin®	500-750 mg IV once daily		
Linezolid	Zyvox®	600 mg IV every 12 hours	Pediatric: 20-30 mg/kg/day IV in two to three divided doses	For MRSA infection
Meropenem	Merrem®	1 g IV every 8 hours	Pediatric: 60 mg/kg/day IV in three divided doses	
Metronidazole	Flagyl®	500 mg IV every 8 hours	Pediatric: 30-50 mg/kg/day IV in three divided doses	
Moxifloxacin	Avelox®	400 mg IV once daily		
Nafcillin	Nafcil®	1-2 g IV every 4-6 hours	Pediatric: 100-200 mg/kg/day IV in four to six equally divided doses	
Oritavancin	• Orbactiv® • Kimyrsa®	1,200 mg IV once with no additional doses (Orbactive® administered over 3 hours and		For MRSA infection

		Kimyrsa® over 1 hour)		
Penicillin G	Pfizerpen® Bicillin® Wycillin®	1-2 million units IV every 4-6 hours	Pediatric: 100,000-200,000 units/kg/day IV in four divided doses[a]	
Piperacillin–tazobactam	Zosyn®	3.375-4.5 g IV every 6 hours	Pediatric: 250-350 mg/kg/day IV in three to four divided doses	
Procaine penicillin G	Bicillin C-R®	0.6-1.2 million units IM every 12 hours	Pediatric: 25,000-50,000 units/kg (maximum 1.2 million units) IM once daily	
Tedizolid	Sivextro®	200 mg IV once daily		For MRSA infection
Telavancin	Vibativ®	10 mg/kg IV once daily		For MRSA infection
Tigecycline	Tigacil®	100 mg IV once, and then 50 mg IV every 12 hours		
Tobramycin	Nebcin®	Traditional: 2 mg/kg loading dose, followed by 1.5 mg/kg IV every 8 hours and guided by measured serum concentrations. Alternative: 5-7 mg/kg IV once daily	Pediatric: 5-7 mg/kg/day IV in three divided doses; doses guided by serum concentrations	
Vancomycin	Vancocin®	30-40 mg/kg/day IV in two divided doses; dosing guided by serum concentrations to achieve 24-hour AUC/MIC ratios of 400-600 for serious MRSA infections	Pediatric: 60-80 mg/kg/day IV in three to four divided doses; doses guided by serum concentrations	For MRSA infection

IM, intramuscularly; MRSA, methicillin-resistant *S. aureus*.

[a] Dosing guidelines in patients with normal renal function.

TABLE 133-6

Drug Monitoring

Drug	Adverse Reaction	Monitoring Parameters	Comments
Aminoglycosides (tobramycin, gentamicin)	Nephrotoxicity	Serum creatinine, urine output, serum concentrations	Extended-interval ("once-daily") dosing potentially associated with less renal toxicity, similar efficacy to traditional dosing. Goal trough concentration <1 μg/mL (mg/L; 2 μmol/L) during extended-interval dosing
Daptomycin	Myopathy	Serum creatine phosphokinase	Most creatinine phosphokinase elevations will be asymptomatic; risk of myopathy may be increased with concomitant use of HMG-coA reductase inhibitors
Imipenem–cilastatin	CNS toxicities, seizures	Serum creatinine, mental status, CNS function	Increased incidence with higher dose, failure to adjust dose/interval for reduced renal function. Increased risk compared with meropenem or doripenem
Linezolid	Myelosuppression, thrombocytopenia, optic/peripheral neuropathy, serotonin syndrome	CBC, vision changes, serum lactate, heart rate, blood pressure, temperature, myoclonus	Myelosuppression and neuropathy more common with prolonged use. Weak MAO inhibitor, serotonin syndrome possible with other serotonergic drugs such as SSRIs and SNRIs
Nafcillin	Interstitial nephritis	Serum creatinine, urine output	Reversible, requires switch to alternative β-lactam
Vancomycin	Nephrotoxicity, infusion reactions	Serum creatinine, urine output, blood pressure, heart rate, serum concentrations	Dose adjustment required for renal dysfunction. Pretreatment and slow infusion may decrease incidence of infusion reaction. Drug concentrations monitored to achieve goal AUC/MIC ratio of 400-600 for serious infections, including necrotizing fasciitis

CBC, complete blood count; MAO, monoamine oxidase; SNRI, serotonin–norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.

Evaluation of Therapeutic Outcomes

Erysipelas generally responds quickly to appropriate antimicrobial therapy. Temperature and white blood cell count should return to normal within 48 to 72 hours. Erythema, edema, and pain also should resolve gradually.

IMPETIGO

③ Impetigo is a superficial skin infection that is seen most commonly in children.[5,23,30,32,33] The infection is generally classified as bullous or nonbullous based on clinical presentation.[5,30,32,33] Impetigo is most common during hot, humid weather, which facilitates microbial colonization of the skin.[4,8,30,32] Minor trauma, such as scratches or insect bites, allows entry of organisms into the superficial layers of skin, and infection ensues.[8,23,30,32] Impetigo is highly communicable and readily spreads through close contact, especially among siblings and children in daycare centers and schools.[8,30,32]

Although historically caused by *S. pyogenes*, *S. aureus* has emerged as a principle cause of impetigo (either alone or in combination with *S. pyogenes*).[23,30,32,33] The bullous form is caused by strains of *S. aureus* capable of producing exfoliative toxins.[23,32,33] The bullous form most frequently affects neonates and children less than 5 years of age,[33,34] and accounts for approximately 30% of all cases of impetigo.[8,32] Similar to other SSTIs, impetigo has been reported to be increasingly due to MRSA.[23,32,33]

CLINICAL PRESENTATION: Impetigo

General

- Exposed skin, especially the face, is the most common site.

Symptoms

- Pruritus is common.
- Systemic signs and symptoms of infection are minimal.
- Weakness, fever, and diarrhea occasionally seen with bullous form.

Signs

Nonbullous:

- Lesions start as small, fluid-filled vesicles.
- Vesicles rapidly develop into pustules that rupture readily.
- Purulent discharge dries to form characteristic golden-yellow crusts.

Bullous:

- Lesions start as vesicles that rapidly progress into bullae containing clear yellow fluid.
- Bullae soon rupture, forming thin, light brown crusts.
- Regional lymph nodes may be enlarged.

Laboratory Tests

- Cultures should be collected for pathogen identification in more severe cases.
- Crusted tops of lesions should be raised to obtain purulent material at the base for culture.
- Open, draining pustules should not be cultured as they may be colonized with skin flora.

Other Diagnostic Tests

- Complete blood cell count often performed, leukocytosis is common.

Treatment: Impetigo

Desired Outcomes

The goals of treatment include relieving discomfort, improving the cosmetic appearance of lesions, preventing further spread of the infection, and preventing recurrence. Preventing transmission to others is also important.[32] Treatments should be effective and inexpensive and have minimal adverse effects.[30,32]

Pharmacologic Therapy

Although impetigo may resolve spontaneously, antimicrobial treatment is indicated to relieve symptoms, prevent formation of new lesions, and prevent complications such as cellulitis. A review of interventions for impetigo by the Cochrane Collaboration found that topical mupirocin and oral antibiotics (except penicillin and erythromycin) were equally effective for the treatment of impetigo[34]; topical mupirocin ointment or retapamulin ointment for 5 days are now recommended as first-line treatment of mild cases of impetigo not involving multiple lesions or the face.[15,23,30,32,33] Penicillinase-resistant penicillins (such as dicloxacillin) are preferred for oral treatment because of the increased incidence of infections caused by *S. aureus*.[15,23,32,33] First-generation cephalosporins (eg, cephalexin) are also commonly used.[15,23,30,32,33] Penicillin, administered as a single intramuscular dose of benzathine penicillin G or as oral penicillin VK, is effective for infections known to be caused by *S. pyogenes* but should not be used for empiric therapy of unknown etiology.[23] Penicillin-allergic patients, or those known to be infected with MRSA, can be treated with clindamycin, doxycycline, or trimethoprim–sulfamethoxazole. The duration of therapy is 7 days.[15,30,33] With proper treatment, healing of skin lesions is rapid and occurs without residual scarring. Removal of crusts by soaking in soap and warm water also may be helpful in providing symptomatic relief.[8,30,32]

Evaluation of Therapeutic Outcomes

Clinical response should be seen within 5 to 7 days of initiating antimicrobial therapy for impetigo. Treatment failures could be a result of noncompliance or antimicrobial resistance. A follow-up culture of exudates should be collected for culture and sensitivity, with treatment modified accordingly.

LYMPHANGITIS

④ Acute lymphangitis is an inflammation involving the subcutaneous lymphatic channels. Lymphangitis usually occurs secondary to puncture wounds, infected blisters, or other skin lesions. Most infections are caused by *S. pyogenes*.[35]

CLINICAL PRESENTATION: Lymphangitis

General

- Lymphadenitis (acute or chronic inflammation of the lymph nodes) may occur when microorganisms reach the lymph nodes.

Symptoms

- Systemic signs and symptoms (ie, fever, chills, malaise, and headache) often develop rapidly before any sign of infection is evident at the initial site of inoculation, or after the initial lesion has subsided.
- Systemic signs and symptoms often are more profound than would be expected based on examination of the cutaneous lesion.

Signs

- Peripheral lesion associated with proximal red linear streaks directed toward the regional lymph nodes is diagnostic of acute lymphangitis.
- Lymph nodes are enlarged and tender.
- Peripheral edema of the involved extremity is present.
- Thrombophlebitis and acute lymphangitis in the lower extremities may be confused because both are associated with red linear streaking and tender areas; however, in thrombophlebitis, no portal of entry is identifiable.

Laboratory Tests

- Cultures of the affected lesions yield negative results.
- Pathogens identified by Gram stain of the initial lesion if done early in the course of the disease.

Other Diagnostic Tests

- Complete blood cell count is often performed as leukocytosis is common.

Treatment: Lymphangitis

Desired Outcomes

The goal of treatment of lymphangitis is rapid eradication of the infection, thereby providing relief of symptoms (pain, tenderness, fever). Prevention of systemic complications is also an important goal as thrombophlebitis and abscess formation are possible. Treatments should be effective and inexpensive and have minimal adverse effects.

Pharmacologic Therapy

Penicillin is the antibiotic of choice. Because these infections are potentially serious and rapidly progressive, initial treatment should be with IV penicillin G 1 to 2 million units every 4 to 6 hours. Parenteral treatment should be continued for 48 to 72 hours, followed by oral penicillin VK for a total of 10 days.[35] Nondrug therapy includes immobilization and elevation of the affected extremity and warm-water soaks every 2 to 4 hours.[35] For penicillin-allergic patients, clindamycin may be used.

Evaluation of Therapeutic Outcomes

Lymphangitis usually responds rapidly to appropriate therapy; signs and symptoms often are decreased markedly or absent within 24 hours of starting antibiotics.

CELLULITIS

⑤ Cellulitis is an acute infectious process that initially affects the epidermis and dermis and may spread subsequently within the superficial fascia.[3,5,12] Cellulitis is considered a serious disease because of the propensity of the infection to spread through lymphatic tissue and to the bloodstream. *S. pyogenes* and *S. aureus* are the most frequent bacterial causes.[3–6,13,21,30] However, many bacteria have been implicated in various types of cellulitis (Table 133-1). Approximately 4 million patients were hospitalized for cellulitis between 1998 and 2006, representing 10% of all infection-related admissions.[3,10,36] Additionally, hospitalizations and costs related to cellulitis and abscess doubled between 1998 and 2013; the number of visits to ambulatory care clinics and emergency rooms doubled from 4.6 million in 1997 to 9.6 million in 2005.[3,5] The rising incidence of infections caused by methicillin-resistant *S. aureus* (MRSA) is a major concern in both the community and hospital settings and is thought to be the major factor contributing to the dramatic increases in both outpatient visits and hospitalizations.[3,5,14,18,37]

Injection drug users are predisposed to several infectious complications, including abscess formation and cellulitis at the site of injection.[3,5,15] These SSTIs are often polymicrobic and originate from skin and/or oropharyngeal flora, as well as from contaminated needles, syringes, and diluents.[3,5,15] *S. aureus*, including MRSA, is the most common pathogen isolated from injection drug users.[3–5,37] Anaerobic bacteria, especially oropharyngeal anaerobes, are also found commonly, particularly in polymicrobial infections.[3,5,15] Outbreaks caused by *Clostridium* species have also been reported in injection drug users.[15]

Acute cellulitis with mixed aerobic and anaerobic pathogens may occur in persons with diabetes, following traumatic injuries, at sites of surgical incisions to the abdomen or perineum, or where host defenses have been otherwise compromised (eg, vascular insufficiency).[3–5,23] In older patients, cellulitis of the lower extremities also may be complicated by thrombophlebitis. Other complications of cellulitis include local abscess, myositis, osteomyelitis, septic arthritis, bacteremia, endocarditis, and sepsis.[3,5,15,23,30] Such complications of cellulitis may occur in approximately 1% of outpatients but as many as 17% of hospitalized patients.[9]

CLINICAL PRESENTATION: Cellulitis

General

- A history of an antecedent wound from minor trauma, abrasion, ulcer, or surgery is often present.

Symptoms

- Patients often experience fever, chills, or malaise and complain that the affected area feels hot and painful.
- Systemic findings such as hypotension, dehydration, and altered mental status are common.

Signs

- Characterized by erythema and edema of the skin.
- Lesions are nonelevated and have poorly defined margins.
- Affected areas are warm to touch.
- Inflammation is present with little or no necrosis or suppuration of soft tissue.
- Lesions may be associated with purulent drainage, exudates, and/or abscesses.
- Tender lymphadenopathy associated with lymphatic involvement is common.

Laboratory Tests

- Cultures of fluid should be collected when purulent drainage, exudates, or abscesses are present.
- Gram stain of fluid obtained by injection and aspiration of 0.5 mL of saline (using a small 22-gauge needle) into the advancing edge of the lesion may aid the microbiologic diagnosis but often yields negative results.
- Diagnosis usually is made on clinical grounds rather than by culture.

Other Diagnostic Tests

- Complete blood cell count is often performed as leukocytosis is common.
- Blood cultures often useful because bacteremia may be present in up to 30% of cases.

Treatment: Cellulitis

Desired Outcomes

The goals of therapy of acute bacterial cellulitis are rapid eradication of the infection and prevention of further complications. Effective treatment of cellulitis includes avoidance of unnecessary antimicrobials that contribute to increased resistance, and minimizing toxicities and cost of therapy.

Drug and Nondrug Management of Cellulitis

Local care of cellulitis includes elevation and immobilization of the involved area to decrease swelling.[3,5,15,23,30] Initial application of cool sterile saline dressings may decrease pain and swelling, and can be followed 1 to 3 days later with moist heat to aid in localization of the cellulitis. Surgical intervention (incision and drainage) is rarely indicated in the treatment of uncomplicated cellulitis, but may play an important role in management of more severe or complicated cases. Antimicrobial therapy is directed against the type of bacteria either documented or suspected to be present based on the clinical presentation and risk factors. Particular attention must be paid to patients with risk factors for more atypical or resistant bacterial pathogens when selecting antibiotics for treatment of cellulitis. Such organisms include particularly MRSA, but also aerobic gram-negative bacteria and anaerobes.

Because staphylococcal and streptococcal cellulitis are indistinguishable clinically,[3–5,30] and because of concern regarding appropriate recognition and treatment of MRSA infections, guidelines from the Infectious Diseases Society of America (IDSA) provide detailed recommendations for empiric antibiotic therapy of cellulitis.[15,27] Antibiotic selection for treatment of cellulitis is chiefly determined by clinical findings such as appearance of the infected lesion and presence of more severe systemic illness. Cellulitis may be broadly classified as either purulent or nonpurulent for purposes of determining likely pathogens and appropriate empiric antibiotic therapy. Purulent cellulitis is defined as infection associated with purulent drainage or exudate in the absence of a simple drainable abscess; the presence of abscesses is also often associated with purulent cellulitis but by definition is the only clinical feature.[4,15,27] Incision and drainage of any abscesses and good wound care are the primary therapies for mild purulent infections when no systemic findings of infection are present. Systemic antibiotic therapy is often unnecessary in such cases.[3–5,27] Antibiotic therapy is recommended along with incision and drainage in patients with more complicated abscesses and/or moderately severe purulent cellulitis including the following: those with systemic signs of infection; multiple sites of infection; rapidly progressive infection in the presence of associated cellulitis; complicating factors such as extremes of age, comorbidities, or immunosuppression; abscesses in areas that are difficult to drain, such as hands, face, and genitalia; or lack of response to previous drainage alone.[3–5,15,23,27] Patients with complicated abscesses and/or moderately severe purulent cellulitis are usually treated as outpatients using orally administered antibiotics with activity against MRSA; infection due to streptococci is less likely in this situation and specific coverage is not required.[3–5,27] Oral agents recommended for moderate purulent cellulitis include trimethoprim–sulfamethoxazole and doxycycline (Fig. 133-1).[3–5,15] Oral linezolid is also recommended in such cases but is more expensive and apparently no more efficacious than other treatment options.[3–5,27,37,38] Tedizolid, an oxazolidinone, is also indicated for the treatment of complicated SSTI. Compared to linezolid, tedizolid may have advantages related to a more convenient dosing schedule and fewer adverse effects and drug interactions. However, tedizolid is likely no more effective than linezolid for SSTI and its role relative to linezolid is still unclear.[15,37,38,39]

Severe purulent cellulitis is defined as purulent infections occurring in patients who have failed incision and drainage plus oral antibiotic therapy, patients with systemic signs of infection (defined as temperature greater than 38°C, heart rate greater than 90 beats/min, respiratory rate greater than 24 breaths/min, or white blood cell count greater than 12,000 [12×10^9/L] or less than 400 cells/μL [0.4×10^9/L]), or immunocompromised patients. Appropriate clinical specimens for culture and susceptibility testing should be collected whenever possible in such patients.[3–5,15,22,27] Patients with severe purulent cellulitis should be hospitalized for empiric treatment with parenteral antibiotics having activity against MRSA. Vancomycin, daptomycin, linezolid or tedizolid, televancin, and ceftaroline are all acceptable treatment options with comparable efficacy in adults (Fig. 133-1).[8,3–6,12,13,15,27,37,38] In children, vancomycin, linezolid, or clindamycin are the preferred treatment options.[3,15,33]

Linezolid, tedizolid, daptomycin, ceftaroline, and telavancin all exhibit excellent activity against resistant gram-positive pathogens.[6,12,37,38,39,40] However, significantly higher cost compared with vancomycin, as well as lack of clearly demonstrated advantages in efficacy, makes them most appropriate for the treatment of complicated or refractory infections, or those documented as caused by multidrug-resistant pathogens, rather than as initial therapy. The availability of orally administered linezolid and tedizolid may provide cost-effective “step-down” options as alternatives to prolonged treatment with parenteral agents for many patients with more complicated infections and/or those patients who require initial hospitalization.[4,6,12,13,37-39]

The appropriate roles of dalbavancin and oritavancin, two newer glycopeptide drugs indicated for the treatment of complicated SSTI and with good activity against MRSA, are not well-defined for the routine management of SSTIs. Dalbavancin exhibits a terminal elimination half-life of approximately 14 days and is administered as a single large dose or two smaller doses given one week apart. Oritavancin has a half-life of approximately 10 days and is administered as a single one-time dose. The ability to provide an entire course of therapy with only one or two doses is attractive in terms of convenience, improved adherence compared to oral therapy, facilitation of early discharge of hospitalized patients, and potential for avoidance of inpatient hospitalization costs through administration in the emergency department, infusion centers, or physician offices. However, drug acquisition costs are higher than other treatment options and there are concerns related to potential lack of patient follow-up for monitoring of severe infections. Although these agents are not routinely used as first-line therapy, they may be considered for individual patients on a case-by-case basis in order to optimize their use.[3–6,12,13,15,23,37,38]

Delafloxacin is a fluoroquinolone with activity against staphylococci including MRSA, streptococci, and gram-negative bacteria including *P. aeruginosa*. Although IV followed by oral delafloxacin is equivalent to vancomycin plus aztreonam in the treatment of ABSSSI, its role is not well-defined and delafloxacin is not routinely recommended for treatment of cellulitis. The ability to transition patients from IV to oral therapy and its broad spectrum of activity may make delafloxacin a potential treatment option for carefully selected patients, particularly those with severe polymicrobial infections.

Carbapenems (ie, imipenem, meropenem, ertapenem, and doripenem) and the penicillin–β-lactamase inhibitor combination antibiotics (ampicillin–sulbactam, piperacillin–tazobactam) is equivalent to standard therapies in adults.[3,8,15] However, the greater cost of these agents without increased efficacy compared with other reliable regimens, particularly given the increasing problem of MRSA, makes them less desirable for empiric therapy except in serious polymicrobic infections.[3,15] Newer β-lactam–β-lactamase inhibitor combination agents such as ceftolozane–tazobactam, ceftazidime–avibactam, and meropenem–vaborbactam have few clinical data in the treatment of SSTIs and should not be used for empiric treatment of severe infections.

Nonpurulent cellulitis is defined as cellulitis without purulent drainage or exudate and no associated abscess. The role of MRSA in these types of infection is not clear, so empiric therapy of nonpurulent cellulitis is directed primarily against Group A β-hemolytic streptococci.[3–5,23] Recommended empiric therapy of mild nonpurulent cellulitis (ie, no focus of purulence or systemic signs of infection) consists of an orally administered β-lactam such as penicillin VK, cephalexin, or dicloxacillin (Fig. 133-1).[3–5,15,21,27] Oral cephalosporins, such as cefadroxil, cefaclor, cefprozil, cefpodoxime proxetil, and cefdinir, are also effective in the treatment of cellulitis but are more expensive.[15,21,23] Oral clindamycin may be used in penicillin-allergic patients.[15,21,23,27] Alternatively, a cephalosporin may be used cautiously for patients without a history of immediate or anaphylactic reactions to penicillin. Patients with moderately severe nonpurulent cellulitis (ie, systemic evidence of infection) or poor adherence to oral therapy should be hospitalized and treated with parenteral antibiotics directed against Group A streptococci. Recommended agents include penicillin VK, ceftriaxone, cefazolin, and clindamycin.[3–5,15,21,33] Hospitalization and treatment with parenteral antibiotics are also recommended for patients with severe nonpurulent cellulitis as indicated by the presence of systemic findings of infection (as previously defined for purulent cellulitis), failure of previous oral antibiotic therapy, immunocompromised states, or presence of clinical signs of deeper infection such as bullae, skin sloughing, hypotension, or organ dysfunction.[3,4,15,21,23] Empiric antibiotics for severe nonpurulent cellulitis should provide a broad spectrum of activity against MRSA and streptococci, as well as gram-negative and anaerobic bacteria. Recommended regimens include vancomycin plus piperacillin–tazobactam, and vancomycin plus imipenem–cilastatin or meropenem.[3,5,15,21,23]

Empiric treatment of MRSA should be considered for patients with either moderate or severe nonpurulent cellulitis that is associated with penetrating trauma, evidence of MRSA infection at another site or nasal colonization with MRSA, injection drug use, or in patients meeting SIRS criteria (fever, tachycardia, tachypnea, or leukocytosis or leukopenia as previously defined).[3,13,15,21,27] Recommended drugs for the coverage of MRSA in this setting are the same as those for purulent cellulitis. Clindamycin has reasonably good activity against β-hemolytic streptococci, but the activities of trimethoprim–sulfamethoxazole and the tetracyclines against this organism are not well-defined.[3,15,23,27] Therefore, if empiric coverage of both MRSA and β-hemolytic streptococci is desired for patients with nonpurulent cellulitis, they should receive clindamycin alone or amoxicillin in combination with trimethoprim–sulfamethoxazole, doxycycline, or minocycline.[3,13,15,23,27] Hospitalized patients with nonpurulent cellulitis who are not initially treated for MRSA should have their antibiotic changed to an agent with activity against MRSA if there is unsatisfactory clinical response.[3,16,23,27] Although often used for treatment of uncomplicated outpatient cellulitis, fluoroquinolones (eg, levofloxacin, moxifloxacin) are not recommended for routine use due to their unnecessarily broad spectrum of activity, concerns for resistance and toxicities, and higher cost compared with other preferred options.

Patients in whom specific pathogens have been identified by culture should have empiric antibiotics narrowed according to susceptibility test results. If documented to be a mild cellulitis secondary to streptococci, oral penicillin VK or intramuscular procaine penicillin G may be administered. Since *S. aureus* susceptibilities are more variable, treatment of documented staphylococcal infections will depend on test results for specific isolates. The usual duration of therapy for outpatient treatment of cellulitis, either purulent or nonpurulent, is 5 days; a longer duration should be considered if the infection has not sufficiently improved within that time.[3,8,15,23,30] A 7 to 14 day course of antibiotics has been recommended for cellulitis in hospitalized patients, but shorter courses (5-7 days) are often as effective as longer courses and should be used whenever possible.[16] In all cases, duration of therapy should be individualized based on patient response.[3,4,15,27]

For cellulitis caused by gram-negative bacilli or a mixture of microorganisms, immediate antimicrobial therapy, as determined by Gram stain, is essential. Surgical debridement of necrotic tissue and drainage may also be appropriate. Gram-negative cellulitis may be treated appropriately with an aminoglycoside (ie, gentamicin or tobramycin), or a first- or second-generation cephalosporin (eg, cephalexin, cefaclor, or cefuroxime). Ceftriaxone, ceftazidime, and fluoroquinolones are also effective in the treatment of cellulitis caused by both gram-negative and gram-positive bacteria.[3,4,8,15] If gram-positive aerobic bacteria are also present on Gram stain, an additional agent such as penicillin G or a penicillinase-resistant penicillin may need to be added to provide coverage against streptococci or staphylococci, respectively, as appropriate.[3,4,27] Addition of an agent active against MRSA (eg, vancomycin) may need to be considered for severe, complicated infections in hospitalized patients.[3,4,6,8,27] Ceftaroline is potentially advantageous in this setting since it has activity against MRSA and streptococci as well as gram-negative aerobic bacteria.

Because some polymicrobic infections may involve anaerobic bacteria, antibiotic therapy may need to be broadened to include agents with good activity against these organisms. Many different treatment regimens are possible depending on the bacteriology of the lesion (Fig. 133-1). Orally administered antibiotics, as monotherapy or in combination regimens, may be appropriately used in the treatment of mild-to-moderate infections in outpatients. Monotherapy or combination regimens of IV antibiotics may be necessary for more severe infections in hospitalized patients. Therapy should be 5 to 7 days in duration, with longer durations potentially needed in patients who do not respond to therapy in that time.[8,3,4,15]

Because gram-negative and mixed aerobic–anaerobic cellulitis can progress quickly to serious tissue damage, therapeutic intervention should be immediate.[8,3,15] If treated early, a rapid response can be seen. Unfortunately, because these infections often occur in patients with compromised immune defenses, they may still progress, even with therapeutic intervention. If the infectious process is secondary to a systemic cause (eg, diabetes), the treatment course often is prolonged and may be associated with high morbidity and mortality.[3,4,8,23]

Infections in injection drug users are treated similar to those in other types of patients.[8,15] Blood cultures must be obtained in these cases because 25% to 35% of patients may be bacteremic.[8,15,22] Also, patients should be assessed for the presence of abscesses; incision, drainage, and culture of these lesions are of extreme importance.[15] Initial antimicrobial therapy while awaiting culture results of abscesses should include broad coverage for gram-negative and anaerobic organisms, in addition to MRSA and streptococci.[8,15,22]

Evaluation of Therapeutic Outcomes

If treated promptly with appropriate antibiotics, the majority of patients with cellulitis are cured rapidly. Culture and sensitivity results should be evaluated carefully for both the adequacy of culture material and the presence of resistant organisms. Additional high-quality samples for culture may be needed for microbiologic analysis. Failure to respond to therapy may also be indicative of an underlying local or systemic problem or a misdiagnosis.

NECROTIZING SOFT-TISSUE INFECTIONS

Necrotizing soft-tissue infections consist of a group of extremely severe infections, associated with high morbidity and mortality, that require early and aggressive surgical debridement in addition to appropriate antibiotics and intensive supportive care.[4–6,23,41-45] Different terms have been used to classify necrotizing infections based on factors such as predisposing conditions, onset of symptoms, pain, skin appearance, etiologic agent, gas production, muscle involvement, and systemic toxicity.[3,4,23,42] However, while many types of necrotizing soft-tissue infections have been designated as unique infectious processes, they all share similar pathophysiologies, clinical features, and treatment approaches.[41-45] The major clinical entities of necrotizing infections are *necrotizing fasciitis* and *clostridial myonecrosis* (gas gangrene).[4,23,41-45]

⑥ Necrotizing fasciitis is a rare but severe infection of the subcutaneous tissue that may be caused by aerobic and/or anaerobic bacteria and results in progressive destruction of the superficial fascia and subcutaneous fat.[4,23,41-45] Type I necrotizing fasciitis is the most common and accounts for approximately 80% of necrotizing soft-tissue infections.[4,23,41–45] It generally occurs after trauma or surgery and involves a mixture of anaerobes (*Bacteroides*, *Peptostreptococcus*) and facultative bacteria (streptococci and Enterobacterales) that act synergistically to cause destruction of fat and fascia.[4,23,41,42] Type I necrotizing fasciitis is also reported more commonly among injection drug users.[41-44] In type I infections, the skin may be spared, and the speed at which the infection spreads (3-5 days) is somewhat slower than that in type II.[23,42] Necrotizing fasciitis affecting the male genitalia is termed *Fournier's gangrene*.[4,41,42] Type II necrotizing fasciitis is caused by virulent strains of *S. pyogenes* and is commonly referred to as *streptococcal gangrene*.[4,23,41-45] This type of infection has often been called "flesh-eating bacteria" by the lay press. Type II infections may occur in young, previously healthy individuals as well as older individuals with underlying diseases.[4,23,41-45] It differs from type I infections in its clinical presentation. Type II infections have rapidly extending necrosis (ie, 24-72 hours) of subcutaneous tissues and skin, gangrene, severe local pain, and systemic toxicity.[41-45] They are also highly associated with an early onset of shock and organ failure and are present in approximately half the cases of streptococcal toxic shock-like syndrome.[41-45] Of note, MRSA is increasingly reported in type II infections, either as a single organism or in combination with streptococci.[4,23,41-43]

Clostridial myonecrosis (type III necrotizing fasciitis) is a necrotizing infection that involves the skeletal muscle.[4,23,41-45] Type III infections account for less than 5% of necrotizing infections.[42] Gas production and muscle necrosis (myonecrosis) are prominent features of this infection, which readily explains why this infection is commonly referred to as *gas gangrene*.[4,23,41-43] The infection advances rapidly, often over a matter of a few hours.[41-45] Most infections occur after surgery or trauma, with *Clostridium perfringens* identified as the most common etiologic agent.[4,23,41-45]

CLINICAL PRESENTATION: Necrotizing Soft-Tissue Infections

General

- Most frequently involve the abdomen, perineum, and lower extremities.
- Predisposing factors such as diabetes mellitus, local trauma or infection, or recent surgery often present.
- Rapid diagnosis is critical due to the aggressive nature and high associated mortality (20%-50%).

Symptoms

- Systemic symptoms generally are marked (eg, fever, chills, and leukocytosis) and may include shock and organ failure, especially in patients with type II infections.
- Pain in the affected area and systemic toxicity are characteristically more pronounced than with cellulitis.

Signs

- May be difficult to differentiate between necrotizing fasciitis and cellulitis early in infection.
- Affected area is initially hot, swollen, and erythematous without sharply demarcated margins.
- Affected area is often shiny, exquisitely tender, and very painful.
- Diffuse swelling of the area is followed by the appearance of bullae filled with clear fluid.
- Rapidly progressive infection with the frequent development of a maroon or violaceous color of the skin after several days.
- Infection may rapidly evolve into a cutaneous gangrene, sometimes with myonecrosis.

Laboratory Tests

- Tissue samples should be obtained for histologic examination, and culture and susceptibility testing.
- Clostridial myonecrosis shows little inflammation on histologic examination.

Other Diagnostic Tests

- Surgical exploration is the best and most rapid means of diagnosing necrotizing infections; computed tomography and magnetic resonance imaging may also be helpful.
- Blood samples should be collected for complete blood cell count and chemistry profile, as well as for bacterial culture.
- Laboratory tests that may aid in the diagnosis of necrotizing infections (LRINEC score) include C-reactive protein, white blood cell count, hemoglobin, sodium, creatinine, and glucose.

Treatment: Necrotizing Soft-tissue Infections

Desired Outcomes

The goals of therapy of acute bacterial cellulitis are rapid eradication of the infection, prevention of further complications, and reduction in mortality. Effective treatment of necrotizing soft-tissue infections includes avoidance of unnecessary antimicrobials that contribute to increased resistance, and minimizing toxicities and cost of therapy.

Management of Necrotizing Infections

Immediate and aggressive surgical debridement of all necrotic tissues is essential in all patients with suspected or confirmed necrotizing fasciitis.[4,15,23,41-45] Initial surgical debridement performed greater than 14 hours after the diagnosis of necrotizing infection was independently associated with increased patient mortality, including a 34-fold increased risk of death in patients with septic shock.[41-45] Patients often require repeated surgical intervention following initial debridement to ensure that all necrotic tissue has been removed.[41-45] Type I necrotizing fasciitis must be empirically treated with broad-spectrum antibiotics that include coverage against streptococci, Enterobacterales, and anaerobes. Piperacillin–tazobactam plus vancomycin is specifically recommended as appropriate empiric therapy of necrotizing fasciitis, although a number of antibiotic regimens are also appropriate to successfully treat necrotizing soft-tissue infections (see Fig. 133-1).[4,15] These antibiotic regimens are generally similar to regimens used for polymicrobic cellulitis.[4,8,23,41-45] Antibiotic therapy can be modified after Gram stain and culture reports are available.

If a diagnosis of either type II (streptococcal) or type III (clostridial) necrotizing fasciitis is established, broad-spectrum empiric therapy should be replaced with the combination of penicillin plus clindamycin.[4,15,23,41-45] Although *S. pyogenes* remains susceptible to penicillin, the combination with clindamycin is more effective.[41,43] Several factors have been postulated to explain the greater efficacy of clindamycin, including a mechanism of action (inhibition of protein synthesis) that may cause decreased production of bacterial exotoxins.[4,23,41-45] In addition, clindamycin has immunomodulatory properties that may account for higher efficacy.[41-45] Clindamycin is also effective against some strains of MRSA.[4,23,42] Linezolid has also been suggested for necrotizing fasciitis due to mechanistic properties that are similar to those of clindamycin, but clinical data are fewer in comparison.[4,23,41,42] Hyperbaric oxygen is potentially beneficial for clostridial myonecrosis, but its use is not currently recommended due to lack of clear evidence of improved patient outcomes.[4,15,23,41–45] Likewise, the use of intravenous immunoglobulin (IVIG) has not yet been proven beneficial in the treatment of necrotizing streptococcal infections and its use is not routinely recommended.[4,15,23,41-45]

Evaluation of Therapeutic Outcomes

Because of the high mortality associated with necrotizing infections, rapid and complete debridement of all devitalized and necrotic tissue is essential. Surgical debridement, coupled with appropriate antimicrobial therapy and supportive measures for management of shock and organ failure, should stabilize the patient. Vital signs and laboratory tests should be monitored carefully for signs of resolution of the infection. Change in antimicrobial therapy or additional surgical debridement may be needed in patients who do not show signs of improvement.

DIABETIC FOOT INFECTIONS

Three major types of foot infections are seen in patients with diabetes: deep abscesses, cellulitis of the dorsum, and mal perforans ulcers.[46,47] Most deep abscesses involve the central plantar space (arch) and are caused by minor penetrating trauma or by an extension of infection of a nail or web space of the toes. Infections of the dorsal area generally arise from infections in the toes that are related to routine care of the nails, nail beds, and calluses of the toes. Mal perforans ulcer is a chronic ulcer of the sole of the foot. The ulcer develops on thickened, hardened calluses over the first or fifth metatarsal. Mal perforans ulcers are associated with neuropathic changes, which are responsible for the misalignment of the weight-bearing bones of the foot.[46,47] Osteomyelitis is one of the most serious complications of diabetic foot infection (DFI) and may occur in 30% to 40% of infections.[26,46,47]

Epidemiology

DFI is among the most common complications of diabetes, accounting for as many as 20% of all hospitalizations in patients with diabetes at an annual cost of $200 to $350 million.[26,46,48] Approximately 25% of patients with diabetes develop a foot ulcer during their lifetime; up to 60% of these ulcers involve significant soft-tissue infection and osteomyelitis is present in up to 40%.[26,46-48] Approximately 71,000 lower-extremity amputations, often sequelae of uncontrolled infection, are performed each year on patients with diabetes; this represents up to 80% of all nontraumatic amputations in the United States.[26,46,48] Approximately 40% of patients with diabetes will have recurrence of an ulcer within 12 months, and 20% of patients will undergo additional surgery or amputation of a second limb within 12 months of an initial amputation.[26,46-48]

Etiology

Mild cases of DFI are often monomicrobial. However, more severe infections are typically polymicrobic; up to 60% of hospitalized patients have polymicrobial infections (Table 133-7).[26,46,47,49,50-53] Wide ranges in the frequency of various bacteria in DFI reflect differences in culture techniques as well as variation among different types and severity of infections. Staphylococci and streptococci are the most common pathogens, although gram-negative bacilli and/or anaerobes occur in up to 50% of cases.[49-53] Although *P. aeruginosa* is an important pathogen in DFI, it is usually reported in less than 10% of wounds and is most commonly associated with more severe infections.[26,50] Obligate anaerobes are also more commonly associated with severe infections in patients with chronic foot ischemia.[26,49,50] MRSA is increasingly important in DFI and has been reported in 10% to 30% of infected wounds.[26,50,51,53,54,55] The presence of MRSA in DFI has been associated with increased risk of treatment failure and worse patient outcomes, but these findings have not been consistent among studies and the clinical relevance of MRSA in this setting is still unclear.[26,47,54]

TABLE 133-7

Bacterial Isolates from Foot Infections in Diabetic Patients

Organisms	Percentage of Isolates
Aerobes	63-100
Gram-positive	24-100
Staphylococcus aureus (all)	10-80
S. aureus (MRSA)	1-37
Streptococcus spp.	3-37
Enterococcus spp.	2-25
Coagulase-negative staphylococci	6-10
Other gram-positive aerobes	0-19
Gram-negative	16-73
Proteus spp.	3-7
Enterobacter spp.	1-9
Escherichia coli	3-10
Klebsiella spp.	1-6
Pseudomonas aeruginosa	1-48
Other gram-negative bacilli	3-13
Anaerobes	1-40
Peptostreptococcus spp.	4-28
Bacteroides fragilis group	2-9
Other *Bacteroides* spp.	3-6
Clostridium spp.	0-2
Other anaerobes	7-19

Data from References 26,46,47,49,50-54,56.

Identifying causative pathogens from cultures of DFI is often difficult. The chronic nature of DFI means that these wounds are often heavily colonized by organisms not playing a role in the infection. Superficial swab cultures are not as reliable as culture specimens obtained from deep tissues or bone via biopsy, tissue scraping (curettage), or needle aspiration of drainage or abscess fluid.[22,47,51,53] Therefore, cultures and sensitivity tests should be done with specimens obtained from a deep culture of the wound base whenever possible. Before the wound is cultured, it should be scrubbed vigorously with saline-moistened sterile gauze to remove any overlying necrotic debris and further debrided as necessary.[22,26,51] Bone cultures should also be performed when there is diagnostic uncertainty regarding the presence of osteomyelitis or when therapeutic decisions are dependent on knowing the exact etiology of infection.[22,26,47,51,53]

Pathophysiology

Three key factors are involved in the development of diabetic foot ulcers: neuropathy, angiopathy and ischemia, and immunologic defects. Any of these disorders can occur in isolation; however, they frequently occur together.[48]

Neuropathic changes to the autonomic nervous system as a consequence of diabetes may affect the motor nerve supply of small intrinsic muscles of the foot, resulting in muscular imbalance, abnormal stresses on tissues and bone, and repetitive injuries.[46,48] Diminished sensory perception causes an absence of pain and unawareness of minor injuries and ulceration. The sympathetic nerve supply may be damaged, resulting in the absence of sweating that may lead to dry cracked skin and secondary infection.[26,46,48]

Atherosclerosis is more common, appears at a younger age, and progresses more rapidly in the persons with diabetes compared with those without. Individuals with diabetes may have problems with both small vessels (microangiopathy) and large vessels (macroangiopathy) that can result in varying degrees of ischemia, ultimately leading to skin breakdown and infection. Peripheral artery disease is present in up to 50% of persons with diabetes and is strongly associated with impaired wound healing.[49]

Persons with diabetes typically have normal humoral immunity, normal levels of immunoglobulins, and normal antibody responses. Patients with diabetes, however, have impaired phagocytosis and intracellular microbicidal function as compared with nondiabetics; this may be related to angiopathy and low tissue levels of oxygen.[26,46,48] These defects in cell-mediated immunity make patients with diabetes more susceptible to certain types of infection and impair the patients' ability to heal wounds adequately.[46-48]

CLINICAL PRESENTATION: Diabetic Foot Infections

General

- Infections are much more extensive than they initially appear.

Symptoms

- Patients with peripheral neuropathy often do not experience pain; simple complaints of swelling or edema are common.

Signs

- Clinical signs of infection may not be present secondary to angiopathy and neuropathy.
- Lesions vary in size and clinical features (eg, erythema, edema, warmth, presence of pus, draining sinuses, pain, and tenderness).
- Foul-smelling odor suggests the presence of anaerobic organisms.
- Temperature may be mildly elevated or normal.

Laboratory Tests

- Specimens for culture and sensitivities should be collected.
- Deep-tissue samples obtained during surgical debridement are most useful for culture and susceptibility testing.
- Wounds must be cultured for both aerobic and anaerobic organisms.

Other Diagnostic Tests

- Possible presence of osteomyelitis must also be assessed via radiograph, bone scan, or both, as appropriate.

Treatment: Diabetic Foot Infections

Desired Outcomes

⑦ The goals of therapy in the management of DFI include the following: (a) successfully treat infected wounds by using effective nondrug and antibiotic therapy; (b) prevent additional infectious complications; (c) preserve as much normal limb function as possible; (d) avoid unnecessary use of antimicrobials that contribute to increased resistance; and (e) minimize toxicities and cost while increasing patient quality of life.

Management

Up to 90% of infections can be treated successfully with a comprehensive treatment approach that includes both wound care and antimicrobial therapy.[26,47,51] After carefully assessing the extent of the lesion and obtaining necessary cultures, necrotic tissue must be thoroughly debrided, with wound drainage and amputation as required. Wounds must be kept clean and dressings changed frequently (two to three times daily). Because of the relationship between hyperglycemia and immune system defects, glycemic control must be maximized to ensure optimal wound healing. In addition, the patient's activities should be restricted initially to bed rest for leg elevation and control of edema, if present. Adequate pressure relief from a foot wound (ie, off-loading) is crucial to the healing process.[26,48,51] Finally, appropriate antimicrobials must be initiated.[26,47,48,51] However, the optimal antimicrobial therapy for DFI has yet to be defined. Broad-spectrum empiric therapy that provides coverage of all possible pathogens is not recommended unless the infection is life- or limb-threatening, assuming that adequate wound care is also being performed.[46-49,51,54] This is particularly true regarding MRSA, *P. aeruginosa*, and anaerobes; the perceived need for empiric coverage of these organisms often leads to use of excessively broad-spectrum drug regimens. Several studies have shown good antimicrobial treatment efficacy despite the fact that the regimens did not have consistently good activity against these particular organisms and no specific regimen has shown clear superiority over another.[46-52,54-56]

Proper selection of empiric antibiotics for DFI begins with thorough patient assessment and classification of the severity of the infection. Specific drug regimens, route of administration, and duration of therapy are all then largely dependent on the severity of infection. Although a number of classification systems are available, the most recent DFI treatment guidelines use those summarized in Table 133-8.[26,46,51] Wounds with no local signs of infection often do not require antibiotic therapy, and the majority of mild, uncomplicated infections can be managed successfully on an outpatient basis with highly bioavailable oral antimicrobials and good wound care (Tables 133-8 and 133-9).[46-49,53] Antibiotics for treatment of mild infections should be largely limited to those with activity against skin flora such as streptococci and methicillin-susceptible *S. aureus* (MSSA), except in those patients with risk factors for infection with other types of pathogens (Fig. 133-2).[46-48,51] Patients with specific risk factors for MRSA (Table 133-9) should empirically receive trimethoprim–sulfamethoxazole or doxycycline orally, while those who have received antibiotics within the past month should also receive empiric antibiotics that provide activity against gram-negative bacilli. Oral antimicrobials should be used cautiously in DFI complicated by osteomyelitis, extensive ulceration, areas of necrosis, or a combination of these. The use of topical antimicrobials, including medical-grade honey, has been advocated for the treatment of DFI in an attempt to minimize the cost of therapy and systemic antibiotic exposure leading to adverse effects and resistance. Although the most recent guidelines allow for consideration of topical therapy in mild infection in selected patients, use of topical agents is quite controversial, inconsistent in proven benefits, and not routinely recommended.[26,47,51,57]

FIGURE 133-2

Recommended treatment algorithm for initial empiric management of mild-to-moderate diabetic foot infections. (GNR, aerobic gram-negative rods; GPC, aerobic gram-positive cocci; MRSA, methicillin-resistant *Staphylococcus aureus*; TMP-SMX, trimethoprim–sulfamethoxazole). [a]May substitute metronidazole in place of cylindamycin.

TABLE 133-8

Classifications and Treatment Strategies for Diabetic Foot Infections of Varying Severity

Clinical Signs/Symptoms of Infection	Infection Severity	Treatment Setting
None	Uninfected	Outpatient management; nonantibiotic wound management only
Local infection present (≥2 of the following): local swelling or induration, erythema, local tenderness or pain, local warmth, purulent discharge		Outpatient or inpatient management according to severity (mild, moderate, or severe) as assessed by additional criteria
Local infection involving only skin and subcutaneous tissue, without involvement of deeper tissues or SIRS criteria present; if erythema is present, must be >0.5 and ≤2 cm around ulcer	Mild	Outpatient management; topical or oral antibiotics
Local infection with erythema >2 cm around ulcer, or involving structures deeper than skin and subcutaneous tissue (eg, abscess, osteomyelitis, septic arthritis, fasciitis); no SIRS criteria present	Moderate	Outpatient (or initial inpatient) management; oral (or initial parenteral) antibiotics
Local infection with ≥2 SIRS criteria: • Temperature >38°C (100.4°F) or <36°C (96.8°F) • HR >90 • RR >20 • WBC >12,000/mm^3 (12 × 10^9/L) or <4,000/mm^3 (4 × 10^9/L), or >10% (0.10) bands	Severe	Inpatient, followed by outpatient, management; initial parenteral antibiotics, followed by switch to oral when possible

Data from Reference 26.

TABLE 133-9

Suggested Antibiotic Regimens for Empiric Treatment of Diabetic Foot Infections

Severity of Infection	Probable Pathogens	Drug(s)[a]	Duration of Therapy
Mild	• *Staphylococcus aureus* (MSSA) • *Streptococcus* spp. • *S. aureus* (MRSA) ○ Patients with history of MRSA infection or colonization in past year ○ Prevalence of MRSA ≥50% in local geographic area ○ Recent hospitalization	• Amoxicillin–clavulanate • Cephalexin • Dicloxacillin • Clindamycin • Levofloxacin • Moxifloxacin[b]	1-2 weeks; may increase up to 4 weeks if infection is slow to resolve
Moderate-to-severe (initially oral or IV antibiotics for moderately severe infections, IV antibiotics for severe infections)	• MSSA • *Streptococcus* spp. • Enterobacterales • Obligate anaerobes	• Ampicillin–Sulbactam • Cefoxitin • Ceftriaxone • Imipenem/cilastatin • Ertapenem	Moderately severe infection: 1-3 weeks; severe infection: 2-4 weeks

		- Levofloxacin - Moxifloxacin - Tigecycline - Levofloxacin or ciprofloxacin + clindamycin	
	MRSA - Patients with history of MRSA infection or colonization in past year - Prevalence of MRSA ≥30% in local geographic area - Recent hospitalization - Infection severe enough that not empirically covering MRSA poses unacceptable risk of treatment failure	Add to one of the above regimens: - Vancomycin - Linezolid - Daptomycin	
	Pseudomonas aeruginosa - Patient has been soaking feet - Patient has previously failed therapy with nonpseudomonal antibiotic regimen - Severe infection	Piperacillin/tazobactam	
	Mixed infections potentially including all of the above	- Cefepime, ceftazidime, or aztreonam + metronidazole or clindamycin + vancomycin[c] - *or* piperacillin–tazobactam or imipenem–cilastatin or meropenem[b] + vancomycin[c]	

[a] Agents not shown in any particular order of preference.

[b] Not specifically recommended in IDSA guidelines but may be appropriate treatment option.

[c] Linezolid or daptomycin may be used in place of vancomycin.

MRSA, methicillin-resistant *S. aureus*; MSSA, methicillin-susceptible *S. aureus.*

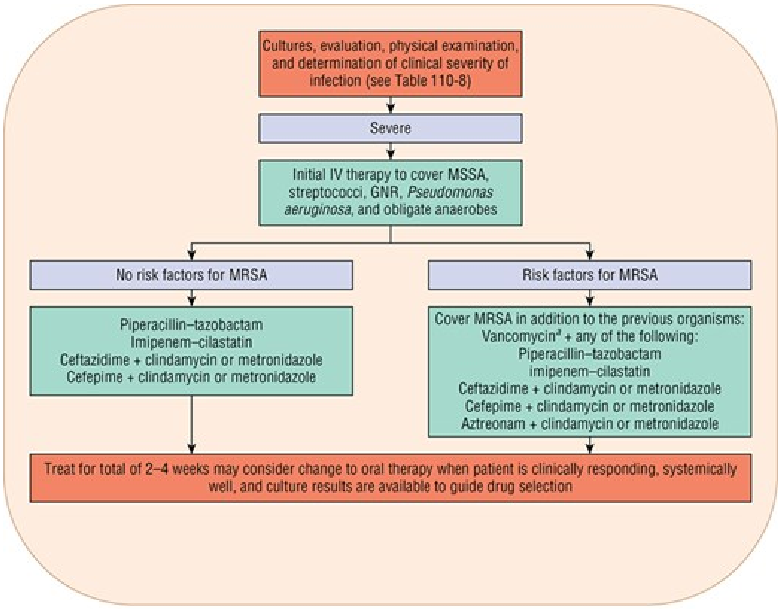
Data from Reference 26.

Appropriate initial therapy for patients with moderate-to-severe infection is also dependent on the presence of specific risk factors that increase the likelihood of infection with more resistant pathogens such as *P. aeruginosa* and MRSA (Table 133-9).[26,46,48,51] Many moderate infections can be successfully treated with orally administered antibiotics that provide activity against MSSA, streptococci, and gram-negative aerobic bacilli; coverage of obligate anaerobes may also be considered in patients with chronic or previously treated wounds (Fig. 133-3).[26,46,48,51] The addition of orally administered agents with activity against MRSA is recommended in patients with moderate or severe infection and specific risk factors for MRSA; such patients may also be considered for hospitalization and initial treatment with parenteral antibiotics in order to ensure adequate antibiotics for potentially more complex infections.[26,46,48,50,51] Patients with more extensive or chronically unhealed wounds, even though assessed as moderate in severity, may also be more appropriately treated initially with parenteral antibiotics in the hospital setting.[47-52]

FIGURE 133-3

Recommended treatment algorithm for initial empiric management of severe diabetic foot infections. (GNR, aerobic gram-negative rods; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-susceptible *S. aureus*)

[a]May substitute linezolid or daptomycin for vancomycin.



Cultures, evaluation, physical examination, and determination of clinical severity of infection (see Table 110-8)
Severe
Initial IV therapy to cover MSSA, streptococci, GNR, *Pseudomonas aeruginosa*, and obligate anaerobes
No risk factors for MRSA
Risk factors for MRSA
Piperacillin–tazobactam
Imipenem–cilastatin
Ceftazidime + clindamycin or metronidazole
Cefepime + clindamycin or metronidazole
Cover MRSA in addition to the previous organisms:
Vancomycin[a] + any of the following:
Piperacillin–tazobactam
imipenem–cilastatin
Ceftazidime + clindamycin or metronidazole
Cefepime + clindamycin or metronidazole
Aztreonam + clindamycin or metronidazole
Treat for total of 2–4 weeks may consider change to oral therapy when patient is clinically responding, systemically well, and culture results are available to guide drug selection

All patients with severe DFI should be hospitalized initially and treated with broad-spectrum IV antibiotics (Table 133-9 and Fig. 133-3).[46-52] Severe infection is considered a risk factor for *P. aeruginosa*, so most patients with severe DFI will be initially started on antipseudomonal antibiotics.[48-51] Many patients will also be initially started on antibiotics that provide activity against MRSA due to risk-versus-benefit considerations, but assessment of risk factors in individual patients is important in order to minimize the use of excessively broad-spectrum antibiotics when possible.

Guidelines for management of DFI include options for both monotherapy and combination regimens (Table 133-9).[26] Monotherapy, along with appropriate medical or surgical management, or both, is often effective in treating DFI, including those in which osteomyelitis is present.[46-52,56] Monotherapy is particularly attractive because of the potential advantages of convenience, cost, and avoidance of toxicities. Microbiologic and clinical cure rates ranging from 60% to 90% may be expected from any of these agents.[46-52,56] Selection of a specific regimen is determined by patient-specific factors including allergies, renal function, history of previous antibiotic use, and cost. In penicillin-allergic patients, metronidazole or clindamycin plus a fluoroquinolone, aztreonam, or possibly a third- or fourth-generation cephalosporin is appropriate.[46-52,56] Vancomycin is also used frequently in severe infections because of its good activity against gram-positive pathogens, with linezolid, daptomycin, and tigecycline specifically recommended as alternatives to vancomycin.[46-52] Tigecycline may be particularly useful in this setting because of its activity against gram-negative aerobes and anaerobic bacteria, thus allowing it to be used as monotherapy for the treatment of mixed infections in patients where coverage of *P. aeruginosa* is not of great concern. Ceftaroline fosamil also has in vitro activity suitable for DFI but has not been studied for this indication. Because many patients already have some degree of diabetic nephropathy that may place them at higher risk of nephrotoxicity, strong recommendations have been made against the use of aminoglycoside antibiotics unless no alternative agents are available.[26,47] When an aminoglycoside is used, care must be taken to avoid further compromising renal function. All antibiotic regimens should be adjusted as necessary for renal dysfunction. There is no defined role for newer broad-spectrum agents such ceftolozane–tazobactam, ceftazidime–avibactam, meropenem–vaborbactam, eravacycline, and delafloxacin; their use in DFI is not recommended.

Duration of therapy for DFI depends on the severity of the infection, ranging from 1 to 2 weeks for mild infections up to 2 to 4 weeks or more for severe infections.[46-52] In the cases of underlying osteomyelitis, treatment should continue for 6 to 12 weeks.[46-52] After healing of the infection has occurred, a well-designed program for the prevention of further infections should be instituted. The use of adjunctive agents such as colony-stimulating factors, growth factors, and hyperbaric oxygen for either prevention or treatment of DFIs is controversial and not widely recommended.[26]

Evaluation of Therapeutic Outcomes

Therapy should be reevaluated carefully after 48 to 72 hours to assess favorable response. Change in therapy (or route of administration, if oral) should be considered if clinical improvement is not observed at this time. For optimal results, drug therapy should be appropriately modified according to information from deep-tissue culture and the clinical condition of the patient. Infections in patients with diabetes often require extended courses of therapy because of impaired host immunity and poor wound healing.

PRESSURE INJURIES

The terms *decubitus ulcer*, *bed sore*, *pressure sore*, and pressure injury are interchangeably, althought pressure injury is now the preferred term.[29,58-60] The decubitus ulcer and the bed sore are types of pressure sores. The term *decubitus ulcer* is derived from the Latin word *decumbere*, meaning “lying down.” Pressure injuruies, however, can develop regardless of a patient’s position.

Numerous systems for classification of pressure injuries have been described. The 2016 recommendations of the National Pressure Ulcer Advisory Panel (NPUAP) are shown in Table 133-10. The NPUAP classification system is most commonly used and illustrates various stages of progression through which a pressure injury may pass.[60]

TABLE 133-10

Pressure Injury Classification

Stage 1	Intact skin with a localized area of nonblanchable erythema. Presence of blanchable erythema or changes in sensation, temperature, or firmness may precede visual changes. Color changes do not include purple or maroon discoloration; these may indicate deep tissue pressure injury.
Stage 2	Partial-thickness loss of skin with exposed dermis. Wound bed is viable, pink or red, moist, and may also present as an intact or ruptured serum-filled blister. Adipose tissue is not visible and deeper tissues are not visible. Granulation tissue, slough, and eschar are not present.
Stage 3[a]	Full-thickness loss of skin, in which adipose tissue is visible in the ulcer and granulation tissue and epibole (rolled wound edges) are often present. Slough and/or eschar may be visible. Depth of tissue damage varies by anatomical location; areas of significant adiposity can develop deep wounds. Undermining and tunneling may occur. Fascia, muscle, tendon, ligament, cartilage, and/or bone are not exposed.
Stage 4[a]	Full-thickness skin and tissue loss with exposed or directly palpable fascia, muscle, tendon, ligament, cartilage, or bone in the ulcer. Slough and/or eschar may be visible. Epibole (rolled edges), undermining, and/or tunneling often occur. Depth varies by anatomical location.
Unstageable[a]	Full-thickness skin and tissue loss in which the extent of tissue damage within the ulcer cannot be confirmed because it is obscured by slough or eschar. If slough or eschar is removed, a stage 3 or stage 4 pressure injury will be revealed.
Deep-tissue pressure injury	Intact or nonintact skin with localized area of persistent nonblanchable deep red, maroon, purple discoloration or epidermal separation revealing a dark wound bed or blood filled blister. Pain and temperature change often precede skin color changes. This injury results from intense and/or prolonged pressure and shear forces at the bone-muscle interface. The wound may evolve rapidly to reveal the actual extent of tissue injury, or may resolve without tissue loss.

[a] Stage 3, stage 4, and unstageable lesions are unlikely to resolve on their own and often require surgical intervention.

Data from Reference 60.

Complications of pressure injuries are common and may be life-threatening. Infection is one of the most serious and most frequently encountered complications of pressure injuries.[58,59] Although most pressure injury wounds are heavily colonized, the majority of these eventually heal.[58,59,61] When true infection is present, however, there is bacterial invasion of previously healthy tissue. Without treatment, an initial small, localized area of ulceration can rapidly progress to large ulcers within days. The visible ulcer is just a small portion of the actual wound[29]; up to 70% of the total wound is below the skin. A pressure-gradient phenomenon is created by which the wound takes on a conical nature; the smallest point is at the skin surface, and the largest portion of the defect is at the base of the ulcer (Fig. 133-4).

FIGURE 133-4

Distribution of forces involved with sore formation in a conical fashion.

Epidemiology

Pressure injuries are most common among chronically debilitated persons, older adults (70% involve persons older than 70 years), and persons with serious spinal cord injury.[29,58,59] Generally, patients who are at risk for pressure injuries are older adults or chronically ill young patients who are immobilized, in either bed or a wheelchair, and who may have altered mental status and/or incontinence.[58,59]

Etiology

Similar to DFIs, a large variety of aerobic gram-positive and gram-negative organisms, as well as anaerobes, frequently are isolated from wound cultures.[24,62] Most pressure-injury related ulcers are heavily colonized with microorganisms, making assessment for infection a clinical challenge.[24,62] Curettage of the ulcer base after debridement provides more reliable culture information than does needle aspiration.[61,62] Biopsy specimens give the most reliable data but may not be practical to obtain. Deep-tissue cultures from different sites may give different results. Cultures collected from pressure ulcers reveal polymicrobial growth. A culture collected by swab is likely to identify surface bacteria colonizing the wound rather than to diagnose the infection.[29,62]

Pathophysiology

Many factors apparently predispose patients to the formation of pressure injuries: paralysis, paresis, immobilization, malnutrition, anemia, infection, and advanced age. Factors thought to be most critical to their formation are pressure, shearing forces, friction, and moisture[29,58,59]; however, there is still a debate as to the exact pathophysiology of pressure injury development.[58,59]

Pressure is the essential element in the formation of pressure injuries.[24,58,59] The areas of highest pressure are generated most often over the bony prominences.[24,58,59] Both the degree of pressure and the length of time that the pressure is applied are important.[58,59]

Shearing occurs when two surfaces move in opposite directions.[24,58,59] This situation can occur when the head of a bed is raised, causing the upper torso to slide downward, transmitting pressure to the sacrum and other areas. This effect results in occlusion or distortion of vessels, leading to compromise of the dermis. At the same time, sitting and gravity create shearing forces; the posterior sacral skin area can become fixed secondary to friction with the bed. The effects of friction and shearing forces combine, resulting in transmission of force to the deep portion of the superficial fascia and leading to further damage of soft-tissue structures.[24,58,59]

Compounding the problems of shearing and friction forces are the macerating effects of excessive moisture in the local environment, resulting from incontinence and perspiration. This factor is of critical importance because when combined with the other forces, it increases the risk of pressure sore formation fivefold.[29,58,59]

CLINICAL PRESENTATION: Pressure Injuries

General

- Most pressure injuries are in the pelvic region and lower extremities; see Fig. 133-5.
- Most common sites: sacral and coccygeal areas, ischial tuberosities, and greater trochanter.

Symptoms

- Patients commonly have other medical problems that may mask signs and symptoms of infection.
- Pain may be present with or without infection; continuous pain may indicate infection.

Signs

- A dark red color on the surface of a pressure injury-related ulcer may indicate local infection.
- Surrounding erythema, swelling, and heat are commonly present with infection.
- Purulent discharge, foul odor, and systemic signs (eg, fever and leukocytosis) of infection may be present.

Laboratory Tests

- Cultures should be collected from either a biopsy or fluid obtained by needle aspiration.

Other Diagnostic Tests

- Complete blood cell count often performed for assessment of potential infection.
- Consider magnetic resonance imaging if suspicious of underlying osteomyelitis.

Figure 133-5

Treatment: Pressure Sores

Desired Outcomes

The primary goal for pressure injuries is prevention. Once pressure injury has developed, the goals of therapy are prevention of complications (ie, infections), preventing injuries from growing larger, and preventing the development of injuries in other locations.[58,59] Eradication of infection should include good wound care and topical therapies, and avoidance of broad-spectrum antimicrobials unless guided by results from appropriately collected cultures or in patients with bacteremia, sepsis, cellulitis, or osteomyelitis.

Drug and Nondrug Management

⑧ Prevention is the single most important aspect in the management of pressure injuries. Skin surveillance and frequent repositioning (ie, pressure reduction) are key in preventing pressure injuries.[29,58,59] Prevention is far easier and less costly than the intensive care necessary for the healing and eventual closure of pressure injuries. Of primary importance, then, is the ability to identify patients who are at high risk so that preventive measures may be instituted. Relief of pressure through proper positioning, and periodic repositioning, is probably the single most important factor in preventing pressure injury formation. Relief for a period of only 5 minutes once every 2 hours gives protection against pressure injury formation.[29,58,59,61] Repositioning seated patients every 15 to 60 minutes is also recommended.[29,58,59] Pressure relief devices such as mattresses or overlays filled with air, water, gel, or foam are helpful in preventing pressure injuries.[29] Cushions and ankle or heel protectors should also be encouraged.[29,59] Skin care and prevention of soilage are also important, with the intent being to keep the surface relatively free of moisture. Patients with problems of incontinence should be cleaned frequently, and efforts should be made to keep the involved areas dry.[29,58,59]

The medical approach to the treatment of pressure injuries depends on the stage of the disease. Medical management is indicated for lesions that are of moderate size and relatively shallow depth (stage 1 or 2 lesions) and are not located over a bony prominence. Depending on their location and severity, from 30% to 80% of these injuries will heal without an operation. Surgical intervention is almost always necessary for ulcers that extend through superficial layers or into bone (stage 3, stage 4, and unstageable lesions).[24,56]

The goal of therapy is to clean and decontaminate the ulcer in order to permit formation of healthy granulation tissue that promotes wound healing or prepare the wound for an operative procedure. The main factors to be considered for successful topical therapy (local care) are (a) relief of pressure, (b) debridement of necrotic tissue as needed, (c) wound cleansing, (d) dressing selection, and (e) prevention, diagnosis, and treatment of infection.[29,58,59,61]

Relief of pressure is important once pressure injury has developed. The same repositioning methods and pressure-reducing devices used for preventive care also apply to treatment.[29,58,59,61]

The goals of debridement and cleansing measures are removal of devitalized tissue and reduction of bacterial contamination, which can slow granulation time and impede healing.[29,58,59,61] Debridement can be accomplished by surgical, mechanical, or chemical means.[24,58,59,61] Surgical debridement rapidly removes necrotic material from the wound and is recommended for urgent situations (eg, cellulitis and sepsis).[29,58,59,61] Mechanical debridement involves wet-to-dry dressing changes in which saline-soaked gauze is applied to the wound; after drying, the gauze is removed and with it any adherent necrotic tissue. Other effective mechanical therapies include hydrotherapy (use of the whirlpool [Hubbard tank] to remove necrotic tissue and debris), wound irrigation, and dextranomers (beads placed in the wound to absorb exudate and bacteria).[24,58,59] Chemical debridement includes enzymatic and autolytic agents. Enzymatic debridement involves application of topical debriding agents to remove devitalized tissue. This method is recommended for patients who cannot tolerate surgery or are in a long-term care or home setting.[29,58,59,61] Autolytic debridement involves the use of synthetic dressings that allow devitalized tissue to self-digest via enzymes present in wound fluids. Autolytic debridement is contraindicated in the treatment of infected pressure injuries.[29,58,59,61]

Pressure injury wounds should be cleaned with normal saline.[24,29,59,61] No cleansing solution or technique has demonstrated greater efficacy on healing.[63] Cleansing agents that are cytotoxic, such as povidone–iodine, iodophor, sodium hypochlorite solution, hydrogen peroxide, and acetic acid, should be avoided.[29,58,59,61] Many of these agents destroy granulation tissue and impair healing. Many different types of dressings are available for pressure injuries.[24] Wound dressing materials should keep the wound moist, allow free exchange of air, act as a physical barrier to bacteria, and prevent physical damage.[24,29,59] Controlled studies of the various types of wound dressings have shown no significant differences in healing outcomes.[58,63] Occlusive dressings (hydrocolloid, such as DuoDERM™ or Tegaderm™) and transparent dressings (eg, 3M Tegaderm™) are not recommended for infected wounds.[24,29,59] If occlusive dressings are used, any infection should be controlled or the dressing frequency increased.

Topical antibiotics (silver sulfadiazine, triple antibiotic) or medical grade honey may be considered for a clean ulcer that is not healing or is producing a moderate amount of exudate despite appropriate care.[29,58,59] When used, topical antibiotics should be limited to a 2-week trial or until additional definitive debridement can be performed, whichever comes first.[29,58,59] Systemic treatment of pressure-related ulcers is generally reserved for infections associated with bacteremia, sepsis, cellulitis, fasciitis, or osteomyelitis.[29,58,61] Empiric therapy for infected pressure sores or associated infectious complications should cover MRSA, anaerobes, enterococci, and more resistant gram-negative bacteria such as *Pseudomonas* (see Table 133-5).[58,59] Thereafter, antibiotics should be guided by results from appropriately collected cultures.

Other nonpharmacologic approaches to shorten the healing time have included the use of hyperbaric oxygenation, hydrotherapy, high-frequency/high-intensity sound waves, and electrotherapy.[29,61] Electrical stimulation is the only adjunctive therapy that is proven effective.[29,61] Various comorbid conditions (diabetes mellitus, smoking, peripheral vascular disease, malnutrition) may impair wound healing. Eliminating or optimizing these factors is recommended, although studies have not demonstrated benefit.[24,59]

Evaluation of Therapeutic Outcomes

With appropriate wound care and antimicrobial therapy, infected pressure injuries can heal. A reduction in erythema, warmth, pain, and other signs and symptoms should be seen in 48 to 72 hours.

ANIMAL AND HUMAN BITE WOUNDS

Approximately half the population in the United States will be bitten by either an animal or another human sometime during their lifetimes.[64-66] Animal bites (typically from dogs or cats) are common causes of injury, particularly to children, and are associated with significant risk of infection without prompt attention and appropriate management. Likewise, human bite wounds are often deceptively severe and frequently require aggressive management to reduce the risk of infectious complications. If left untreated, severe soft-tissue infection and osteomyelitis may occur, possibly requiring extensive debridement or amputation.

Epidemiology

Dog bites account for approximately 75% to 90% of all animal bite wounds requiring medical attention.[65] The Centers for Disease Control and Prevention reports that approximately 330,000 individuals seek emergency room attention for dog bites annually; rates of dog bite–related injuries are highest in children aged 5 to 9 years.[66] Most dog bites are to the extremities,[65] but the majority of bites to children less than 5 years of age are to the face and neck.[66] Cat bites are the second most common cause of bite wounds in the United States, accounting for up to 20% of all animal bites.[64] Cat bites occur most commonly on the upper extremities and face, with most injuries reported in women and older adults.[64,67] Human bites are the third most frequent type of bites requiring medical attention.

Infection rates after dog and cat bites are estimated at 20% overall. However, infection may occur in up to 30% to 80% of serious cat bites, a rate more than double those seen with dog bites.[64,67] Also, bite wounds to the hands become infected in 30% to 40% of cases.[64] Patients at greatest risk of acquiring animal bite–related infection have had a puncture wound (usually to the hand), have not sought medical attention within 8 hours of the injury, and are older than 50 years of age.[64,65,67]

Infected human bites can occur as bites from the teeth or from blows to the mouth (clenched-fist injuries). Bites by others can occur to any part of the body, but most often involve the hands. Infectious complications occur in 10% to 50% of patients with human bites.[67]

Etiology

Infections in bite wounds are caused predominantly by mouth flora from the animal or human biter, and from the victim's own skin flora (Table 133-11).[64,65,67-71] Most infections are polymicrobial, with a median of three to nine bacterial isolates per culture.[67-71] *Pasteurella* is the most frequent isolate from both dog and cat bites. *Pasteurella multocida* is part of the normal oral flora of up to 90% of cats; dog bites more commonly involve *P. canis* (approximately 26% of infections).[64,65,67,69] Tularemia (*Pasteurella tularensis*) and cat scratch disease (*Bartonella henselae*) have also been transmitted by cat bites, while rabies is associated with dog bites, particularly in developing countries.[64,65,69,70,72] Human bite wounds are notable for potential involvement of *Eikenella corrodens* in approximately 30% of infections.

TABLE 133-11

Bacterial Isolates from Infections in Animal and Human Bite Wounds

Organisms	Percentage of Isolates	
	Dog and Cat	Human
Aerobes	74-90	44

Data from References 67-70.

Pathophysiology

Animal bites have great potential for infection owing to the pressure that can be exerted during the bite and the vast number of potential pathogens that make up the normal oral flora.[64,65,67-70] Cats' teeth are slender and extremely sharp. Their teeth easily penetrate into bones and joints, resulting in a higher incidence of septic arthritis and osteomyelitis.[67-70] Although a dog's teeth may not be as sharp, they can exert a pressure of 200 to 450 lb/in.^{2} (~1,400-3,100 kPa) and therefore result in a serious crush injury with much devitalized tissue.[64,65,67-70] In addition, the polymicrobic (aerobic and anaerobic) nature of animal bites provides a synergistic relationship, thus making an infection harder to eradicate.[68]

Human bites are more serious and more prone to infection than animal bites, particularly clenched-fist injuries.[68] While the force of a punch may break a bone or sever a tendon or nerve, it most often causes a breach in the capsule of the metacarpophalangeal joint, leading to direct inoculation of bacteria into the joint or bone.[68,70] When the hand is relaxed, the tendons carry bacteria into deeper spaces of the hand, resulting in more extensive infection.[68,70]

CLINICAL PRESENTATION: Bite Wounds

General

Animal bites:

- Only general wound care is required for most patients with dog bites who present early (<12 hours) after injury; infection is more likely in patients presenting late (≥12 hours) after injury.

Human bites:

- Most patients with clenched-fist injuries present for medical care after infection is already established.

Symptoms

- Patients often seek medical care for infection-related complaints (ie, pain, purulent discharge, swelling) at the site of the injury.
- Wounds often have a purulent discharge, and decreased range of motion may be present.

Signs

- Erythema, swelling, and clear or purulent discharge at site of infected wound.

Animal bites:

- If *P. multocida* is present, a rapidly progressing cellulitis is observed within 24 to 48 hours of initial injury.
- Fever is often absent.
- Adenopathy or lymphangitis is uncommon.

Human bites:

- Lymphadenopathy is common.
- In clenched-fist injuries, edema may limit the ability of tendons to glide in their sheaths, thereby limiting a joint's range of motion.

Laboratory Tests

- Samples for bacterial cultures (aerobic and anaerobic) should be obtained from infected wounds.
- Wounds seen <8 hours or more than 24 hours after injury that show no signs of infection may not need to be cultured.
- White blood cell counts should be monitored for resolution of infection if initially elevated.

Other Diagnostic Tests

- Radiographic evaluation should be performed if damage to a bone or joint is suspected.

Treatment: Bite Wounds

Desired Outcomes

The goals of therapy of bite wounds, whether caused by animals or humans, are twofold: to provide effective prophylaxis against infection, when appropriate, and to achieve rapid eradication of established infection and prevent further complications. Effective treatment of bite wounds includes avoidance of unnecessary antimicrobials that contribute to increased resistance, and minimizing toxicities and cost of therapy.

Management of Bite Wounds

9 Bite wounds should be irrigated thoroughly with a copious volume of sterile water or saline, and the wound washed vigorously with soap or povidone–iodine in order to reduce the bacterial count in the wound.[64,65,67,70] Surgical debridement and immobilization of the affected area are often required in dog and human bites associated with more extensive tissue injury. Clinical failures due to edema have occurred despite appropriate antibiotic therapy.[64] Therefore, it is important to stress to patients that the affected area should be elevated for several days or until edema has resolved. In the case of animal bites, an immunization history of the animal should be obtained. It is also important for the patient's tetanus immune status to be determined. Because transmission of viruses (HIV, herpes, hepatitis B and C) is a possibility with human bites, information about the biter is important. Although the possibility of acquiring HIV through saliva alone is believed to be unlikely, the presence of virus-containing blood in the saliva makes disease transmission possible.[73] Bite victims exposed to blood-tainted saliva may be offered antiretroviral chemoprophylaxis, but each case should be individually assessed based on the potential for significant exposure and potential risks and benefits of antiretroviral therapy.[73]

Patients with clenched-fist injuries should be seen by a specialist in hand care to evaluate for penetration into the synovium, joint capsule, and bone.[15,68] Primary closure for human bites generally is not recommended. Tetanus toxoid and antitoxin may be indicated.

10 All patients with human bite injuries should receive prophylactic antibiotic therapy ("early preemptive therapy") for 3 to 5 days due to high infection risk (Table 133-4).[70,71] Prophylactic antimicrobial agents should be given as soon as possible to all patients, regardless of the appearance of the wound, unless it can be documented that the wound does not involve hands, feet, or joints and penetrates no deeper than the epidermis.[15,70]

The role of prophylactic antimicrobial therapy for early, noninfected animal bite wounds remains controversial.[15,64,65,67,68,70] Recommendations from the IDSA suggest that prophylactic or early preemptive therapy seems to provide only marginal benefit for most patients in the absence of specific factors that increase the risk of infection.[15] The decision to administer prophylactic antibiotics is therefore based on an assessment of wound severity and host immune competence. Specifically, prophylaxis is more strongly recommended in patients with the following factors associated with increased risk for infection: immunocompromised; asplenic; advanced liver disease; preexisting or resultant edema of the affected area; moderate-to-severe bite-related injuries, especially to the hands or face; deep puncture wounds that cannot be adequately irrigated; or bite injuries that have penetrated the periosteum or joint capsule.[15,65] A 3- to 5-day course of prophylactic antibiotics is recommended when such therapy is considered to be appropriate.[15,65,67,68,70]

Empiric antibiotics for the treatment of established infection of bite wounds should be directed at a variety of aerobic and anaerobic flora (Table 133-4). Amoxicillin–clavulanic acid is most commonly recommended for oral outpatient therapy due to excellent activity against all likely pathogens, including *Pasteurella* and *Eikenella*.[15,64,65,67,68,70] Alternative oral agents include moxifloxacin or doxycycline alone; or trimethoprim–sulfamethoxazole, levofloxacin, ciprofloxacin, or a second- or third-generation cephalosporin in combination with metronidazole or clindamycin to provide activity against oropharyngeal anaerobes.[15,64,65,67,68,70] Although the combination of penicillin VK plus dicloxacillin has been recommended traditionally for the treatment of bite wounds, its use has become less common in favor of other alternatives. Failure to provide adequate initial treatment of bite wounds results in treatment failures and increased need for hospitalization for parenteral antibiotics.[15,64,65,67,68-70]

Hospitalization for minor wounds is unnecessary if surgical repair of vital structures is not needed. Patients with clenched-fist or other serious bite injuries and severe resultant infection may be considered for IV antibiotics. Treatment options for patients requiring IV therapy include β-lactam–β-lactamase inhibitor combinations (ampicillin–sulbactam, piperacillin–tazobactam), second-generation cephalosporins with antianaerobic activity (eg, cefoxitin), and ertapenem.[15,70] The combination of doxycycline or fluoroquinolone with metronidazole or clindamycin may be used in patients with severe β-lactam allergies. The length of antimicrobial therapy depends on the severity of the injury/infection. However, therapy should generally be continued for 7 to 14 days.[15,64,74]

Tetanus does not occur commonly after dog bites; however, it is possible. If the immunization history of a patient with anything other than a clean, minor wound is unknown, or if the last known vaccination was longer than 10 years ago, tetanus–diphtheria (TD) toxoids should be administered.[74] Both TD toxoids and tetanus immune globulin should be administered to patients who have never been immunized.[70,75]

Because the rabies virus can be transmitted via saliva, rabies may be a potential complication of a bite. When the symptoms of rabies develop after a bite, the prognosis for survival is poor. Roughly 3% of rabies cases documented in animals were in dogs (the most frequent vectors are skunks, raccoons, and bats).[72,76] In the United States, recommendations for postexposure prophylaxis after a dog bite depend on the health of the dog. If the animal is healthy and able to be observed for a 10-day period, active prophylaxis is only required if the dog develops signs of rabies.[67,72] If the dog is known or suspected to be rabid, postexposure procedures should be initiated; current treatment guidelines should be consulted for appropriate management recommendations.[72,76] Outside of the United States, locally applicable guidelines such as those from the World Health Organization should be consulted.[77]

Evaluation of Therapeutic Outcomes

Evaluation of treatment for either animal or human bites should follow the same general guidelines. Bite victims treated on an outpatient basis with oral antimicrobials should be followed up within 24 hours by either phone or office visit.[15] Hospitalization or change to IV therapy should be considered if the infection has progressed. For hospitalized patients with no improvement in signs and symptoms following 24 hours of appropriate therapy, surgical debridement may be needed. Physical therapy may be needed to improve complications such as residual joint stiffness and loss of function, particularly after human bites involving clenched-fist injuries.

ABBREVIATIONS

ABSSSI	acute bacterial skin and skin structure infection

SELF-ASSESSMENT QUESTIONS

1. A 26-year-old male presents to the outpatient clinic complaining of a sore area on his upper back. He said it started as just one sore that was red and tender. On physical examination, several discrete nodules are present that are fluctuant, painful, and surrounded by areas of erythema and edema 1 to 2 cm in diameter. The man states that he is allergic to penicillin, although he does not know the type of reaction that he had previously. His temperature is 101.3°F (38.5°C); other vital signs are within normal limits. His white blood cell count is elevated at 14,300 cells/μL (14.3 x 10^9/L). The most appropriate initial therapy for this patient would be:

   A. Incision and drainage only

   B. Incision and drainage, followed by oral linezolid

   C. Incision and drainage, followed by oral doxycycline

   D. Incision and drainage, followed by intravenous vancomycin

2. A 76-year-old man presents to the emergency department with complaints of a burning pain on his lower leg. Physical examination reveals an erythematous, edematous lesion with a raised border that is sharply demarcated from uninfected skin. The man stated that he felt like he had the flu (fever, tired) before the pain began. His vital signs showed a temperature of 101°F (38.3°C) and a CBC revealed a white blood cell count of 15,100 cells/μL (15.1 x 10^9/L). The man states that he is allergic to erythromycin (it made him sick to his stomach). The most appropriate therapy for this patient would be:

   A. Oral dicloxacillin

   B. Oral clarithromycin

   C. Oral trimethoprim–sulfamethoxazole

   D. Oral penicillin VK

3. A 3-year-old girl is brought to the clinic with complaints of itchy blisters on her face. Her face has three small areas (approximately 15 cm^2 total) of erythema with a mixture of small vesicles filled with clear serous fluid and some larger pustules. Thin golden-yellow crusts of previously ruptured vesicles also cover her face. The child is afebrile, has a normal complete blood count and no known drug allergies. The most appropriate therapy

for this patient would be:

A. Oral dicloxacillin

B. Incision and drainage alone with no antibiotics

C. Topical retapamulin ointment

D. Oral penicillin VK

4. A 15-year-old male is brought to the emergency department by his parents with complaints of fever, chills, and headache. The young man stated that several days ago he had developed a blister on his right hand from pitching baseballs during practice. On physical examination, a bright red, narrow streak extends from the blister to his armpit. Regional lymph nodes are enlarged and tender. A complete blood count was performed which showed his white blood cell count to be elevated. The most appropriate therapy for this patient would be:

   A. Oral ciprofloxacin

   B. Topical mupirocin ointment

   C. Intravenous penicillin G

   D. Intravenous vancomycin

5. A 32-year-old female presents to her family physician complaining that her lower leg feels hot and painful. Physical examination shows the lower leg to have erythema, edema, and it is very warm to the touch. The erythematous area is nonelevated and has poorly defined margins. There is no drainage or exudates and no evidence of abscesses. She has no recollection of any trauma or injury to the area. The woman has normal vital signs and her complete blood count is normal. She has no known allergies. The most appropriate empiric therapy for this patient would be:

   A. Oral dicloxacillin

   B. Oral trimethoprim–sulfamethoxazole

   C. Oral penicillin VK + clindamycin

   D. Oral levofloxacin

6. A 24-year-old female presents to her family clinician complaining of a sore she thought might be from a spider bite. Physical examination reveals a purulent lesion on her lower left leg, surrounded by a 1 cm diameter area of redness and swelling. The patient is afebrile and has a normal white blood cell count. She has no known allergies. The most appropriate therapy for this patient would be:

   A. Incision and drainage of the lesion with no antibiotics required

   B. Incision and drainage of the lesion, followed by penicillin VK

   C. Incision and drainage of the lesion, followed by oral ciprofloxacin

   D. Incision and drainage of the lesion, followed by oral trimethoprim–sulfamethoxazole

7. A 54-year-old obese male presents to the emergency department complaining of severe pain in his left lower leg. His leg is hot, swollen and erythematous without any sharp margins; most of the calf from ankle to knee is affected. The lesion is remarkable for a deep cut 4 cm in length which is draining a yellowish, purulent-looking fluid. The patients states that he injured himself at home when he was cleaning out his garage and was cut by a piece of sheet metal. Vital signs reveal a high temperature (104°F [40.0 °C]) and a complete blood count revealed an elevated white blood count (22,000 cells/mm^3 [22 x 10^9/L]). He has no known allergies. Along with proper wound care, the most appropriate therapy for this patient would be:

   A. Oral cephalexin

B. Oral trimethoprim–sulfamethoxazole

C. Oral amoxicillin–clavulanate

D. Oral levofloxacin

8. A 68-year-old female presents to the diabetes clinic for a routine visit. Her past medical history is significant for Type 2 diabetes mellitus, hyperlipidemia, hypertension, and chronic renal insufficiency. Vital signs showed an elevated blood pressure; an elevated glucose was noted on a chemistry panel. Physical examination reveals a small ulcer on the sole of her right foot. The lesion is erythematous, with the presence of pus and a foul-smelling odor. The patient has allergies to penicillin, ceftriaxone (difficulty breathing with both), and sulfa (rash). She has received multiple courses of antibiotic therapy previously, but the wound has never completely healed. The clinician counsels the patient on the importance of glucose and blood pressure control, as well as self-examination and care of her feet. He also initiates antimicrobial therapy for the infection on her foot, which he judges to be mild in severity. The most appropriate therapy for this patient would be:

A. Oral amoxicillin–clavulanic acid

B. Oral cephalexin

C. Oral moxifloxacin

D. Oral trimethoprim–sulfamethoxazole

9. One week later, the patient in the preceding question returns with no improvement in her ulcer. She states that she has been complianting in taking her therapy as prescribed. The clinician obtains a small aspirated sample for culture and sensitivity. The Gram stain shows many white blood cells and many gram-positive cocci in clusters. The culture grew methicillin-resistant *Staphylococcus aureus* (MRSA), which was resistant to penicillin, cephalexin, and erythromycin, but sensitive to clindamycin, doxycycline, levofloxacin, gentamicin, trimethoprim–sulfamethoxazole, and vancomycin. Anaerobic cultures were still pending. Appropriate management of this patient at this time would be:

A. Switch therapy to oral doxycycline

B. Switch therapy to intravenous gentamicin

C. Switch therapy to oral trimethoprim–sulfamethoxazole

D. Switch therapy to intravenous vancomycin

10. A 55-year-old male with a history of poorly controlled Type 1 diabetes mellitus is admitted to the hospital with suspected necrotizing fasciitis involving the perineum and lower abdomen. The affected area is extremely erythematous, swollen and taut, hot to the touch, and exquisitely painful. The patient has a temperature of 103.6°F (39.8°C) and a white blood cell count of 22,000 cells/µL (22 x 10^9/L). He has no known drug allergies. The most appropriate initiation therapy of this patient's infection would be:

A. Intravenous piperacillin-tazobactam

B. Intravenous ceftriaxone plus linezolid

C. Intravenous penicillin G plus clindamycin

D. Intravenous meropenem plus vancomycin

11. The most important aspect in the prevention of pressure injuries is:

A. Eliminating friction

B. Eliminating moisture

C. Eliminating pressure

D. Eliminating stress

12. An 8-year-old female is brought to the emergency department immediately after being bitten on the right side of her face by a neighbor's dog. The bite wound involves multiple deep puncture wounds and some significant tearing of the surrounding tissues. The most appropriate management of this patient's wound would be:

A. Proper wound care alone, no antibiotics needed

B. Oral antibiotic prophylaxis for 3 to 5 days

C. Oral antibiotic prophylaxis for 7 to 10 days

D. Tetanus–diphtheria toxoids and rabies prophylaxis, no antibiotics needed

13. The most appropriate therapy for an infected dog or cat bite would be:

A. Oral amoxicillin–clavulanic acid

B. Oral cephalexin

C. Oral penicillin VK + clindamycin

D. Intravenous vancomycin

14. A 16-year-old male is brought to the emergency department with a human bite wound to his arm suffered three hours ago during a fight at school. The wound shows no signs of infection at this time. The most appropriate therapy for this patient would be:

A. Oral amoxicillin–clavulanic acid for 3 to 5 days

B. Oral cephalexin for 5 to 10 days

C. Oral clindamycin for 7 to 10 days

D. No antimicrobial therapy at this time

15. Antimicrobial therapy for infections resulting from human clenched-fist injuries should include agents with antimicrobial activity against the following organism(s):

A. CA-MRSA

B. *Eikenella corrodens*, *Staphylococcus aureus*, and anaerobes

C. *Eikenella corrodens*, *Pasteurella multocida*, and *Staphylococcus aureus*

D. *Pasteurella multocida*, *Staphylococcus aureus*, and *Streptococcus pyogenes*

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** The presence of multiple furuncles accompanied by fever and leukocytosis should be managed with incision and drainage plus with oral antibiotics such as doxycycline that provide coverage against *Staphylococcus aureus*. See the Folliculitis, Furuncles, and Carbuncles (Treatment) section for more information.

2. **D.** The intense pain, erythematous lesion with sharply demarcated, raised border and systemic findings are consistent with erysipelas. Appropriate treatment of erysipelas includes antibiotics such as oral penicillin VK that are targeted against streptococci. See the Erysipelas (Clinical Presentation

and Treatment) sections for more information.

3. **A.** This infection is consistent with impetigo. Although a relatively small surface area is affected, lesions involving the face should be treated with systemic antistaphylococcal agents such as dicloxacillin. See the Impetigo (Treatment) section for more information.

4. **C.** Initial treatment of lymphangitis should consist of intravenous penicillin G for 48 to 72 hours, followed by oral penicillin VK. See the Lymphangitis (Treatment) section for more information.

5. **A.** This patient has mild nonpurulent cellulitis and should be treated with antibiotics that provide coverage against Group A streptococci and methicillin-susceptible *Staphylococcus aureus*. See the Cellulitis (Treatment) section for more information.

6. **A.** Incision and drainage alone, without antibiotic treatment, should be sufficient for initial management of this mild purulent cellulitis without evidence of more severe infection such as fever or leukocytosis. See the Cellulitis (Treatment) section for more information.

7. **B.** This patient has a more severe purulent cellulitis with evidence of systemic involvement including high fever and significant leukocytosis. Initial management should include treatment with antibiotics that provide coverage against streptococci and staphylococci including CA-MRSA. See the Cellulitis (Treatment) section of the chapter for more information.

8. **C.** This patient has previously received multiple courses of antibiotics, so antibiotics for this mild diabetic foot infection should include coverage for gram-negative bacilli as well as gram-positive cocci. Moxifloxacin would be the most appropriate choice in this case given the patient's previous history of apparent drug allergies. See the Diabetic Foot Infection (Treatment) section for more information.

9. **A.** The culture is positive for methicillin-resistant *S. aureus*, therefore patient should be switched to oral therapy that provides coverage against this pathogen. Doxycycline would be the most appropriate choice. See the Diabetic Foot Infection (Treatment) section for more information.

10. **D.** Appropriate initial antibiotic therapy of necrotizing fasciitis includes broad-spectrum coverage of gram-positive cocci, gram-negative bacilli, and anaerobes. The combination of meropenem and vancomycin provides the most appropriate spectrum of activity in this situation. See the Necrotizing Soft-Tissue Infection (Treatment) section for more information.

11. **C.** Although friction and moisture also play roles, elimination of pressure is the most important strategy to reduce development of pressure injuries. See the Pressure Injuries (Pathophysiology and Treatment) sections for more information.

12. **B.** Although controversial, moderate-to-severe bite wound injuries to the face are considered an appropriate indication for a 3- to 5-day course of prophylactic antibiotics. See the Animal and Human Bite Wounds (Treatment) section for more information.

13. **A.** Amoxicillin–clavulanic acid is most commonly recommended for oral outpatient therapy of infected dog and cat bites due to excellent activity against all likely pathogens, including *Pasteurella* and *Eikenella*. See the Animal and Human Bite Wounds (Treatment) section for more information.

14. **A.** Antibiotic prophylaxis should be considered for all patients with significant human bite wounds due to the high risk of subsequent infection. Amoxicillin–clavulanate is a commonly recommended agent and the usual duration of prophylaxis is 3 to 5 days. See the Animal and Human Bite Wounds (Treatment) section for more information.

15. **B.** *Eikenella corrodens*, *Staphylococcus aureus*, and anaerobes are pathogens commonly associated with human bite wounds. *Pasteurella* species are more commonly associated with animal bites, and CA-MRSA does not need to be routinely covered in human bite wounds.

See the Animal and Human Bite Wounds (Treatment) section for more information.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 134: Bacteremia and Infective Endocarditis

Daniel B. Chastain

KEY CONCEPTS

KEY CONCEPTS

① Bacteremia, defined as detection of bacteria in the bloodstream, is most often caused by a focal (primary) source of infection and may be complicated by the development of secondary (metastatic) foci, including infective endocarditis.

② Infective endocarditis usually occurs secondary to a bloodstream infection in adult patients with specific risk factors (eg, injection drug use, heart failure, valvular disease, and healthcare exposure) and those with implanted cardiac material (eg, prosthetic heart valves).

③ A wide variety of pathogens may cause bacteremia, which is dependent on the patient population, primary source of infection, and geographic region.

④ Three groups of organisms cause most cases of infective endocarditis: staphylococci, streptococci, and enterococci.

⑤ The clinical presentation of bacteremia and infective endocarditis is highly variable and non-specific, but ranges from asymptomatic to hemodynamic instability and organ dysfunction.

⑥ Diagnosis of bacteremia and infective endocarditis requires the integration of clinical, laboratory, and diagnostic findings.

⑦ In patients with suspected or confirmed bacteremia, empirical antibacterial therapy should target the usual pathogens at the site(s) of suspected primary source(s) of infection and then be deescalated based on organism identification and susceptibility testing.

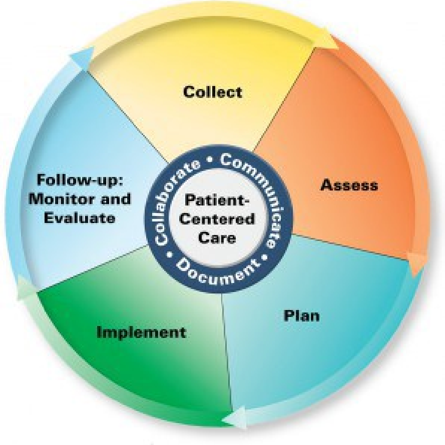
⑧ Treatment of infective endocarditis involves isolation of the infecting pathogen and determination of antimicrobial susceptibilities, followed by parenteral antimicrobial therapy for an extended period.

⑨ Source control which may include drainage, debridement, device removal, and definitive reconstructive manners is a critical component in managing patients with bacteremia.

⑩ Identification and susceptibility testing of the pathogen should guide definitive therapy in patients with bacteremia or infective endocarditis, but in most cases, β-lactams, such as penicillin G (or ceftriaxone), nafcillin, and ampicillin, remain the drugs of choice for streptococcal, staphylococcal, and enterococcal bacteremia and endocarditis, respectively.

PATIENT CARE PROCESS

Patient Care Process for Bacteremia and Infective Endocarditis



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

The image shows the five fundamental steps included in The Pharmacist's Care Process endorsed by the Joint Commission for Pharmacy Practitioners (2014). The tagline of this process reads collaborate, communicate, and document. The five fundamental steps listed here are collect, assess, plan, implement, and follow-up: monitor and evaluate. All these steps are listed in a circular block diagram.

Collect

- Patient characteristics (eg, age, sex, height, weight, pregnancy status, allergies)
- Patient history (eg, past medical, surgical, family)
- Social history (eg, ethanol/IV drug use, recent travel, home residence, exposure to animals) and dietary habits, including intake of unpasteurized dairy products
- Current medication use, including prescription, nonprescription, and other substances, with emphasis on previous inpatient and outpatient antimicrobial use
- Objective data
  - Temperature, blood pressure, respiratory rate, complete blood count (eg, white blood cell count, red blood cell count, hemoglobin, platelets), chemistry panel (eg, serum creatinine), urinalysis
  - Results from blood and/or valve tissue cultures and specialized testing (eg, serology, polymerase chain reaction)
  - Diagnostic testing (eg, electrocardiograph, chest radiograph, echocardiography)

Assess

- Identify risk factors (eg, immunocompromised status, recent dental procedure, central venous catheter, IV drug abuse, dietary habits) (see Tables 134-1 and 134-2)
- Assess signs and symptoms (eg, temperature >100.4°F [38°C], [see Clinical Presentation box], radiographic evidence, pathogen identification, physical examination findings)
- Determine potential infectious etiologies and likely primary (focal) source of infection based on patient history, current and previous antimicrobial use, risk factors, microbiologic data, and diagnostic testing
- Interpret positive blood cultures to determine whether the organism(s) is of clinical significance or contamination (see Table 134-3)
- Determine the need for source control (eg, drainage, debridement, device removal, and definitive reconstructive manners) in patients with bacteremia and surgical intervention (eg, heart failure, persistent bacteremia, persistent vegetation) in patients with infective endocarditis

- Identify patients with underlying high-risk cardiac complications that would be candidates for antimicrobial prophylaxis

Plan[*]

- Determine the most appropriate empirical antimicrobial therapy, including dose, route, and frequency, based on patient characteristics, history, risk factors, and current and previous antimicrobial therapy
- Deescalate empirical therapy to an evidence-based regimen, including dose, route, frequency, and duration (see Tables 134-4 to 134-10), based on microbiologic and specialized testing results
- Develop monitoring parameters to assess efficacy and safety (eg, toxicities)
- Select evidence-based prophylaxis, including dose, route, and frequency (see Table 134-11)

Implement

- Provide patient education regarding all elements of treatment plan
- Initiate and deescalate antimicrobial therapy as appropriate
- Select an appropriate duration of therapy based on microbiologic and specialized testing results
- Develop an outpatient antimicrobial therapy (OPAT) plan at hospital discharge, including dose, route, frequency, and any necessary laboratory tests

Follow-up: Monitor and Evaluate

- Monitor for resolution of signs and symptoms of bacteremia and infective endocarditis
- Monitor results from blood and/or valve tissue cultures and specialized testing
- Monitor for the presence of antimicrobial related-adverse effects and toxicities
- Provide patient education regarding antimicrobial prophylaxis for infective endocarditis

[*] *Collaborate with patient, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

A 35-year-old man with a medical history of diabetes mellitus and injection drug use but no known drug allergies was admitted with diabetic ketoacidosis and left foot cellulitis associated with purulent drainage for which he was started on IV vancomycin and ampicillin/sulbactam. His cellulitis progressed over the next 3 days prompting magnetic resonance imaging (MRI) to be performed which revealed an abscess within the skin and subcutaneous fat, along the dorsum of the foot involving the metatarsals and phalanges consistent with osteomyelitis. He was taken to the operating room for debridement. Operating room cultures and blood cultures obtained on each day of hospitalization grew methicillin-susceptible *Staphylococcus aureus* (MSSA). Postoperatively, he has clinically improved and is anxious to be discharged.

Vital signs and laboratory values from today:

1.9 m, 89.6 kg

96.9°F (36.1 °C), 95 beats/min, 17 breaths/min, 100% on room air, 110/53 mm Hg

Q1. Do you agree with this antibacterial regimen? If not, what alternative antibacterial regimen (drug/dose/route/duration) and monitoring plan do you recommend? Please explain rationale.

Q2. What was this patient's most likely primary source of infection? Does this patient need any additional diagnostic tests prior to developing a final plan? If so, please identify and explain rationale.

Q3. Does this patient meet criteria for uncomplicated or complicated *S. aureus* bacteremia? Please explain rationale.

Q4. Assuming the next set of blood cultures are sterile, what antibacterial regimen (drug/dose/route/duration) and monitoring plan do you recommend for outpatient treatment? Please explain rationale.

INTRODUCTION

① Bacteremia reflects the presence of bacteria in the bloodstream, an otherwise sterile environment, which is identified based on the detection of any true-positive blood culture (Chapter e126, "Laboratory Tests to Direct Antimicrobial Pharmacotherapy").[1] Introduction of bacteria into blood is frequently caused by a focal (primary) source of infection, such as respiratory tract infections (Chapter 129, "Lower Respiratory Tract Infections"), intra-abdominal infections (Chapter 137, "Intra-abdominal Infections"), urinary tract infections (Chapter 139, "Urinary Tract Infections"), as well as bone and joint infections (Chapter 141, "Bone and Joint Infections"), but may also occur due to indwelling devices, medical procedures, or daily activities, such as oral hygiene. In select cases, a primary source cannot be identified. Bacteremia may be further complicated by the development of a systemic inflammatory response syndrome (SIRS) (Chapter 142, "Sepsis and Septic Shock"), or (metastatic) secondary foci, including infective endocarditis in 3% to 8% of cases.

Endocarditis is an inflammation of the endocardium, the membrane lining the chambers of the heart and covering the cusps of the heart valves.[2,3] More commonly, *infective endocarditis* refers to infection of the heart valves by various microorganisms after entry into the bloodstream. Although it typically affects native valves, it may also involve non-valvular areas or implanted material (eg, prosthetic heart valves, cardiac defibrillators, pacemakers, and vascular catheters). Bacteria primarily cause infective endocarditis, but fungi and a variety of other microorganisms can lead to the disease.[2,4] In most cases, infective endocarditis occurs secondary to a bloodstream infection, which originated from a primary source of infection (eg, bacterial endocarditis is secondary to a bacteremia originating from a primary source of infection).

Infective endocarditis is best classified based on the etiologic organism, anatomic site of infection, and pathogenic risk factors.[2,5,6] Infective endocarditis is often referred to as *acute* or *subacute* depending on the pace and severity of the clinical presentation. The acute, fulminating form is associated with high fevers and systemic toxicity. Virulent bacteria, such as *Staphylococcus aureus*, frequently cause this syndrome, and if untreated, death may occur within days to weeks. On the other hand, subacute infective endocarditis is more indolent, caused by less virulent organisms, such as viridans group streptococci, and usually occurs in patients with preexisting valvular heart disease. Infection may also occur following surgical insertion of a prosthetic heart valve, resulting in prosthetic valve infective endocarditis (PVE), or insertion of a cardiac implantable electronic device, resulting in cardiac device infective endocarditis (CDIE).[7,8]

EPIDEMIOLOGY

In the United States, the incidence of bacteremia ranges from 113 to 204 per 100,000 persons and is associated with high rates of morbidity and mortality.[1,9] The epidemiology of bacteremia is difficult to characterize due to differences in study design, definitions used for community- and healthcare-associated bacteremia, as well as the overlap with numerous clinical syndromes.[10] However, patient population, geographic region, and infection prevention practices affect the etiology and rate of bacteremia. For example, in the United States, the annual incidence of *Staphylococcus aureus* bacteremia ranges from 38 to 46 per 100,000 person-years compared to 10 to 30 per 100,000 person-years elsewhere.[11,12]

Risk factors for developing bacteremia are generally non-specific, but some are more specific for individual pathogens or groups of pathogens than others (Table 134-1).[13,14] For example, persons who inject drugs (PWID) have a significantly increased risk for invasive methicillin resistant *S. aureus* (MRSA) bacteremia compared to others. Alternatively, patients who undergo urogenital surgeries are at increased risk for developing gram-negative bacteremia postoperatively.

Table 134-1

Risk Factors for Bacteremia

- Advanced age
- Chronic liver disease
- Diabetes mellitus
- End-stage renal disease on hemodialysis
- Functional or anatomic asplenia
- HIV infection
- Immunosuppressive medications
- Indwelling prostheses (eg, vascular catheters, surgically implanted materials, and orthopedic prostheses)
- Intravenous drug use
- Malignancies
- Malnutrition and hypoalbuminemia (less than 3 g/dL [30 g/L])
- Neutropenia
- Peripheral vascular disease
- Receipt of corticosteroids
- Recent procedures (eg, urogenital surgery, prostate biopsy, endoscopic retrograde cholangiopancreatography)
- Solid organ transplant
- Stem cell transplant
- Trauma or loss of skin integrity
- Urinary retention

Data from References 12–14

Though the overall incidence of infective endocarditis has remained stabled in the United States, the prevalence of PWID has increased while the prevalence of patients with traditional risk factors has decreased.[15–17] Infective endocarditis is more common in men and primarily affects older patients likely due to an aging population with high rates of valvular disease and valve replacement surgery (increasing rates of healthcare-associated infective endocarditis). Most cases occur in individuals older than 60 years of age, and it is less common in children.[18–20] Native valve infective endocarditis (NVE) occurs in 71% to 78% of cases, whereas PVE and CDIE account for 13% to 17% and 3% to 5% of cases, respectively.[6,16,21] PWID are also at high risk and account for 5% to 13% of cases. Other conditions associated with a higher incidence of infective endocarditis include diabetes mellitus, long-term hemodialysis, and poor dental hygiene.[6,20]

② Most persons with infective endocarditis have risk factors, such as preexisting cardiac valvular abnormalities. Many types of structural heart disease result in turbulent blood flow that increases the risk for infective endocarditis. A predisposing risk factor, however, may be absent in up to 25% of cases (Table 134-2).[5,6,8,20,21]

Table 134-2

Risk Factors for Infective Endocarditis

- Presence of a prosthetic valve (highest risk)
- Previous infective endocarditis (highest risk)
- Healthcare-related exposure (high risk)
- Congenital heart disease (CHD)
- Advanced age
- Chronic IV access
- Diabetes mellitus
- Acquired valvular dysfunction (eg, rheumatic heart disease)
- Cardiac implantable device
- Chronic heart failure
- Mitral valve prolapse with regurgitation
- Intravenous drug use
- HIV infection
- Poor dentition and/or oral hygiene

Data from References 5,6,8,20,21.

Rheumatic heart disease was a prevalent risk factor for infective endocarditis, but the incidence of this disease continues to decline. The risk of infective endocarditis in persons with mitral valve prolapse and regurgitation is small; however, because the condition is prevalent, it is an important contributor to the overall number of infective endocarditis cases.[22] The risk of PVE is highest in the first 3 months after valve replacement and occurs in 1% to 3% of patients during the first postoperative year.[20,23]

ETIOLOGY

③ *Escherichia coli*, *Klebsiella* spp., *Pseudomonas aeruginosa*, *S. aureus*, *Enterococcus* spp., and *Streptococcus pneumoniae* are most often identified in patients with bacteremia from high income countries with the addition of *Salmonella* spp. in developing regions.[10] Historically, the etiology differed by whether the onset is community- or healthcare-acquired (eg, *S. pneumoniae* and *E. coli* are most often associated with community-acquired cases whereas *P. aeruginosa* is associated with healthcare-exposure) as well as the primary source of infection. However, a significant number of patients in the ambulatory care setting have frequent interaction with the healthcare system due to receipt of immunosuppressive medications, oftentimes necessitating vascular catheters, use of ambulatory surgery centers, and overall increasing age of the population. As a result, distinction between community- and healthcare-acquired has become less clear.[24] Alternatively, primary source of infection differs, whereby urinary tract infections are more common in community-acquired cases while vascular catheters are more often implicated in patients who develop bacteremia in healthcare settings.[25]

Table 134-4

Sources for Common Causes of Bacteremia

Enterobacterales (eg, *E. coli*, *Klebsiella* spp., *Enterobacter* spp., *Serratia* spp., *Citrobacter* spp.)	• Genitourinary tract • Gastrointestinal tract • Respiratory tract (in hospitalized patients) • Translocation from the gastrointestinal or genitourinary tract due to disruption or procedure • Vascular catheter-related (if applicable)
Pseudomonas aeruginosa	• Respiratory tract (in hospitalized patients) • Vascular catheter- or prostheses-related (if applicable) • Genitourinary tract • Wounds
Staphylococcus aureus	• Wounds • Vascular catheter- or prostheses-related (if applicable) • Post-surgical • Injection drug use
Coagulase negative staphylococci	• Vascular catheter- or prostheses-related (if applicable) • Post-surgical
Enterococcus spp.	• Translocation from the gastrointestinal tract due to disruption or procedure • Genitourinary tract (eg, UTI, prostatitis) • Vascular catheter- or prostheses-related (if applicable)
Viridans group streptococci	• Oral mucosa
Anaerobes	• Oral mucosa • Gastrointestinal tract • Genitourinary tract

Data from References 48

④ Nearly every organism causing human disease may cause infective endocarditis, but three groups of organisms result in a majority of cases: staphylococci, streptococci, and enterococci (Table 134-12).[4–6,26] The incidence of staphylococci, particularly *S. aureus*, continues to increase primarily due to healthcare exposure and intravenous drug use, surpassing viridans group streptococci as the leading cause of infective endocarditis.[5,21,26] Staphylococci (*S. aureus* and coagulase-negative staphylococci) are the most common cause of PVE within the first year after valve surgery, and *S. aureus* is common in PWID. In general, streptococci cause infective endocarditis in patients with community-acquired disease and underlying cardiac abnormalities, such as mitral valve prolapse or rheumatic heart disease. Enterococcal endocarditis tends to follow genitourinary manipulations or obstetric procedures.[23] Although polymicrobial infective endocarditis is uncommon, it is encountered most often in PWID.[5] There are many exceptions to the preceding generalizations; thus, isolation of the causative pathogen and determination of its antimicrobial susceptibilities offer the best chance for successful therapy.

TABLE 134-12

Etiologic Organisms in Infective Endocarditis[a]

Agent	Percentage of Cases
Staphylococci	30-70
• *S. aureus* (coagulase positive)	20-68
• Coagulase negative	3-26
Streptococci	9-38
• Viridans group streptococci	10-28
• Other streptococci	3-14
Enterococci	5-18
Gram-negative aerobic bacilli	1.5-13
Fungi	1-9
Miscellaneous bacteria	less than 5
Polymicrobial infections	1-2
"Culture negative"	5-17

[a] Values encompass community-acquired, healthcare-associated, native valve, and prosthetic valve infective endocarditis.

Data from References 4,6,17,26.

The mitral and aortic valves are affected most commonly in cases involving a single valve. Subacute endocarditis tends to involve the mitral valve, whereas acute disease often involves the aortic valve. Up to 35% of cases involve concomitant infections of both the aortic and the mitral valves. Infection of the tricuspid valve is less common, with most of these cases occurring in PWID. It is rare for the pulmonary valve to be infected.[23,26]

Although outcomes for infective endocarditis have improved with rapid diagnosis, appropriate treatment (eg, antimicrobial therapy, surgery, or both), and prompt recognition of complications should they arise, in-hospital mortality remains approximately 20%, while 6-month mortality is 30%.[19] Factors associated with increased mortality include heart failure, increasing age, endocarditis caused by resistant organisms, such as gram-negative bacteria, or fungi, left-sided endocarditis caused by *S. aureus*, paravalvular complications, healthcare-acquired infection, and PVE.[5,6,26] The presence of heart failure has the greatest negative impact on the short-term prognosis.[5] For left-sided NVE, mortality rates range from 15% to 45%; lower rates (4%-16%) occur with community-acquired disease that is most commonly caused by viridans group streptococci, while higher rates (25%-45%) occur with healthcare-associated disease that is more commonly caused by enterococci and staphylococci. Even higher rates of mortality are seen with unusually encountered organisms (eg, mortality rates greater than 80% for fungi).[5,6] The mortality rate for right-sided infective endocarditis in PWID is generally low (eg, less than 10%).[5] For those who relapse after treatment for infective endocarditis, most will do so within the first 2 months after discontinuation of antimicrobials. Relapse rates for viridans group streptococcus are generally low (2%), whereas relapse is more likely in those with enterococcal infection (8%-20%) and PVE (10%-15%).[23] Despite appropriate treatment and recovery, the risk of morbidity and mortality following infective endocarditis persists for years, with a 5-year mortality rate of approximately 45%.[27] Morbidity remains elevated because of a greater likelihood of recurrent infective endocarditis, heart failure, and embolism or, if a valve is replaced, the risk of anticoagulation, valve thrombosis, or additional valve surgery.[28]

PATHOPHYSIOLOGY

The pathophysiology of bacteremia is multifactorial and may result from numerous causes such as daily oral hygiene, medical procedures, injection drug use, or seeding the bloodstream from focal (primary) source of infection, but the risk varies considerably between syndromes (Tables 134-3 and 134-13).[1,29,30] As a result, bacteremia is frequently considered a secondary infection originating from the focal source (eg, respiratory tract, intra-abdominal tract), but approximately 10% of cases are categorized as primary bacteremia in which bacteria are directly introduced into the bloodstream without an obvious primary source (eg, injection drug use, vascular catheter insertion).[31] Identification of the primary source is critical to making therapeutic decisions.

Table 134-3

Interpretation of Positive Blood Cultures

True pathogens	• β-Hemolytic streptococci • *Bacteroides* spp. • Enterobacterales • *Fusobacterium* spp. • *Haemophilus influenzae* • *Listeria monocytogenes* • *Neisseria meningitidis* • *Pseudomonas aeruginosa* • *Staphylococcus aureus* • *Streptococcus pneumoniae* • Yeast
Possible pathogens	• *Clostridium* spp. • *Enterococcus* spp. • Viridans group streptococci
Unlikely pathogens	• *Bacillus* spp. • Coagulase-negative staphylococci[a] • *Corynebacterium* spp. • *Cutibacterium acnes* • *Micrococcus* spp.

[a] Probability of being a true pathogen increases in the setting of a vascular catheter

Data from References 38,40

Table 134-13

Probability of Bacteremia in Various Clinical Scenarios

High (greater than 50%)	• Discitis and vertebral osteomyelitis • Epidural abscesses • Acute, non-traumatic native septic arthritis • Meningitis • Septic shock • Catheter-related bloodstream infections • Endovascular infections (eg, infective endocarditis, septic thrombophlebitis, vascular graft infections)
Moderate (21%-50%)	• Severe sepsis • Acute pyelonephritis • Cholangitis • Community acquired pneumonia, severe • Pyogenic liver abscesses • Rigors/chills in a febrile patient • Non-vascular shunt (eg, ventriculoperitoneal shunt) infections
Low to moderate (10%-20%)	• Cellulitis in patients with comorbidities • Ventilator-associated pneumonia
Low (less than 10%)	• Uncomplicated cellulitis • Cystitis • Prostatitis • Community acquired pneumonia, non-severe • Hospital-acquired pneumonia
Very low (less than 5%)	• Fever within 48 hours postoperatively • Isolated fever in general medicine patients

Data from References 1,29,30.

Skin and mucosal membranes of the respiratory and gastrointestinal tract serve as the first barrier to defense against bacterial invasion into the bloodstream.[29] In some cases, the host immune response can eradicate bacteria that enter the bloodstream which results in a transient, benign condition. However, if bacteria are able to overcome the host immune response (patients with turbulent cardiac blood flow, foreign or prosthetic material, or when host defense mechanisms fail due to inherent or acquired immune deficits), bacteria can then disseminate throughout the body via hematogenous spread leading to a systemic infection and inducing an inflammatory response. Both transient and persistent bacteremia can lead to secondary metastatic infections involving the meninges, pericardium, kidneys, vertebrae, joints, as well as the heart valves resulting in infective endocarditis.

The development of infective endocarditis via hematogenous spread, the most common route, requires the sequential occurrence of several factors. These components are complex and not fully elucidated.[32,33]

1. *The endothelial surface of the heart is damaged.* This injury occurs with turbulent blood flow associated with the valvular lesions previously described.

2. *Platelet and fibrin deposition occurs on the abnormal epithelial surface.* These platelet-fibrin deposits form a "sterile vegetation," which is referred to as *non-bacterial thrombotic endocarditis*.
3. *Bacteremia gives organisms access to the endocardial surface.* Transient bacteremia commonly follows certain dental, GI, urologic, and gynecologic procedures. Staphylococci, viridans group streptococci, and enterococci are most likely to adhere to non-bacterial thrombotic endocarditis, probably because of production of specific adherence factors such as adhesins for staphylococci and dextran by some oral streptococci. Gram-negative bacteria rarely adhere to heart valves and are uncommon causes of infective endocarditis.
4. *After colonization of the endothelial surface, a "vegetation" of fibrin, platelets, and bacteria forms.* As the vegetation matures, a protective cover of fibrin and platelets protects bacteria from host immune response. This allows unimpeded bacterial growth to concentrations as high as 10^9 to 10^{11} organisms per gram of tissue, in addition to biofilm formation.

The pathogenesis of early PVE or CDIE differs from infective endocarditis acquired by the hematogenous route because surgery may directly inoculate prosthetic material with bacteria from the patient's skin or operating room personnel.[26,34] In the case of early PVE, a recently placed non-endothelialized valve is more susceptible to bacterial colonization than are native valves. Bacteria also may colonize the new valve from contaminated bypass pumps, cannulas, and pacemakers or from a nosocomial bacteremia subsequent to an intravascular catheter.[8,23,26] The mechanism of bacterial colonization and pathogenesis in late PVE is similar to NVE.[23]

One or more vegetations, varying in size from a few millimeters to centimeters, may be seen in a patient with infective endocarditis. Bacteria within the vegetation grow slowly and are protected from antimicrobials and host defenses. The adverse effects of infective endocarditis and the resulting lesions can be far-reaching and include the following: local perivalvular damage, embolization of septic fragments with potential hematogenous seeding of remote sites, and formation of antibody complexes.[23,32]

Formation of vegetations may destroy valvular tissue, and continued destruction can lead to acute heart failure in 50% to 60% of cases via perforation of the valve leaflet, rupture of the chordae tendineae or papillary muscle, or, for patients with PVE, valve dehiscence.[35,36] Occasionally, valvular stenosis may occur. Abscesses can develop in the valve ring or in myocardial tissue itself, potentially involving cardiac conduction tissue. Even with resolution of the process, fibrosis of tissue with some residual dysfunction is possible.

Vegetations may be friable, and fragments may be released downstream. These infected particles, termed *septic emboli*, can result in organ abscess or infarction. Septic emboli from right-sided endocarditis commonly lodge in the lungs, causing pulmonary abscesses. Emboli from left-sided vegetations commonly affect organs with high blood flow such as the kidneys, spleen, and brain.[5,32]

Circulating immune complexes consisting of antigen, antibody, and complement may deposit in organs, producing local inflammation, and damage them (eg, glomerulonephritis in the kidneys). Other potential pathologic changes that result from immune-complex deposition or septic emboli include the development of "mycotic" aneurysms (although the aneurysm is usually bacterial in origin, not fungal), cerebral infarction, splenic infarction and abscess, and skin manifestations such as petechiae, Osler's nodes, and Janeway lesions.[23,32]

CLINICAL PRESENTATION

Bacteremia

⑤ Clinical manifestations of bacteremia vary but may involve fever, chills, rigors, altered hemodynamics, shock, coagulation disorders, cutaneous findings (eg, ulcerations), and a documented or suspected primary source of infection.[1,25] Patients with bacteremia may be normothermic with a normal white blood cell count as neither leukocytosis nor fever (≥ 38°C) alone or in combination predict the presence of bacteremia.[30] However, rigors and shaking chills increased the likelihood of bacteremia. Symptoms may reflect the primary focus of infection and depend on whether other organs or organ systems are involved. Past medical and surgical history may also impact patient complaints upon presentation. In some cases, bacteremia may evoke an inflammatory response resulting in sepsis, but not all cases of bacteremia progress to sepsis.

Infective Endocarditis

⑤ The clinical presentation of infective endocarditis is highly variable and non-specific. Fever is the most common finding, in more than 90% of patients, and is often accompanied by other vague symptoms (Clinical Presentation).[35,36] Heart murmurs are found in most patients (approximately 85%), most often preexisting, with some documented as new or changing. Infective endocarditis usually begins insidiously and worsens gradually. Patients may present with non-specific findings such as fever, chills, weakness, dyspnea, cough, night sweats, weight loss, or malaise. In contrast, patients with acute disease, such as PWID and those with *S. aureus* infective endocarditis, may appear with classic signs of sepsis.

Splenomegaly is an uncommon finding in acute infective endocarditis, due to improved diagnostics and antimicrobial therapy, but it occurs more frequently in patients with subacute infective endocarditis. Other important clinical signs may include the following peripheral manifestations (“stigmata”) of endocarditis[19,26,32]:

1. Osler’s nodes: 2 to 15 mm painful, tender, purplish or erythematous subcutaneous papules or nodules on the pads of the fingers and toes due to embolism, immunologic phenomena, or both occurring in less than 5% of cases.
2. Janeway lesions: Hemorrhagic, painless plaques on the palms of the hands or soles of the feet due to embolism occurring in less than 5% of cases.
3. Splinter hemorrhages: Thin, linear hemorrhages found under the nail beds of the fingers or toes.
4. Petechiae: 1 to 2 mm in diameter, erythematous, painless, non-blanching, hemorrhagic lesions most often visualized on the anterior trunk, buccal mucosa and palate, and conjunctivae that resolve after a few days.
5. Clubbing of the fingers: Proliferative changes in the soft tissues about the terminal phalanges observed in long-standing endocarditis.
6. Roth’s spots: Retinal infarct with central pallor and surrounding hemorrhage.
7. Emboli: Embolic phenomena occur in up to one-third of cases and may result in significant complications. Right-sided endocarditis may result in pulmonary emboli, causing pleuritic pain with hemoptysis. Left-sided endocarditis can result in renal artery emboli causing flank pain with hematuria, splenic artery emboli causing abdominal pain, and cerebral emboli, which may result in hemiplegia or alteration in mental status.

Patients with infective endocarditis typically have laboratory abnormalities; however, none of these changes is specific for the disease. Anemia (normochromic, normocytic), thrombocytopenia, and leukocytosis may be present. The white blood cell count is often normal or only slightly elevated, sometimes with a mild left shift. Acute bacterial endocarditis, however, may present with an elevated white blood cell count, consistent with a fulminant infection. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) may be elevated in approximately 60% of patients. Often the urinalysis shows proteinuria and microscopic hematuria, which may occur in 50% to 65% and 30% to 60% of patients, respectively.[32]

CLINICAL PRESENTATION: Infective Endocarditis

General

The clinical presentation of infective endocarditis is highly variable and non-specific

Symptoms

The patient may complain of fever, chills, weakness, dyspnea, cough, night sweats, weight loss, and/or malaise

Signs

Fever is common, as is a heart murmur (sometimes new or changing). The patient may have congestive heart failure, cardiac conduction abnormalities, cerebral manifestations, embolic phenomenon, splenomegaly, or skin manifestations (eg, Osler's no des, Janeway lesions)

Laboratory Tests

The patient's white blood cell count may be normal or only slightly elevated

Non-specific findings include anemia (normochromic, normocytic), thrombocytopenia, an elevated erythrocyte sedimentation rate or C-reactive protein, and altered urinalysis (proteinuria/microscopic hematuria)

Other Diagnostic Tests

An electrocardiogram, chest radiograph or computed tomography, and echocardiogram are commonly performed. Echocardiography to determine the presence of valvular vegetations plays a key role in the diagnosis of infective endocarditis; it should be performed in all suspected cases

Diagnosis

Bacteremia

⑥ Bacteremia is diagnosed by detection of organism(s) from blood cultures (Chapter e126). Ideally, at least two sets of blood cultures, where each set consists of one aerobic bottle and one anaerobic bottle (3 sets are necessary in cases of infective endocarditis) is obtained prior to administration of antibacterial therapy to lessen the risk of false-negative results.[5,37] Each set of blood cultures should be collected by a trained phlebotomist from separate venipuncture sites that have been disinfected rather than vascular catheters due to a decreased risk of contamination from normal skin flora. Upper extremity vessels are preferred over lower extremity vessels or those affected by dermatologic diseases.[38]

Interpretation of positive blood cultures represents a challenging task to determine the clinical significance of the organism(s) identified, especially in the case of normal skin flora which can cause bacteremia in the right clinical setting (eg, intravascular catheter infections). Single blood culture sets should be avoided due to decreased sensitivity as the cumulative yield of true pathogens increases with the number of blood cultures[39]. In addition, collection of blood cultures after receipt of antibacterial therapy significantly decreases the sensitivity of blood cultures.[37]

When assessing significance of positive blood cultures, the number of positive cultures and the total number of cultures obtained, organism(s) isolated, site(s) of collection, and likelihood of bacteremia must be considered.[38,40] Detection of certain organisms (eg, *S. aureus*, *S. pneumoniae*, Enterobacterales, yeast) should always be considered clinically significant, whereas other organisms may represent clinically significant pathogens or contaminants depending on the clinical status of the patient (Table 134-3).

Infective Endocarditis

⑥ The signs and symptoms of infective endocarditis are not specific, and the diagnosis is often unclear. The identification of infective endocarditis requires the integration of clinical, laboratory, and echocardiographic findings. The Modified Duke Criteria include major and minor variables (Table 134-14).[41,42] Based on the number of major and minor criteria that are fulfilled, patients suspected of infective endocarditis are categorized into three separate groups: definite infective endocarditis, possible infective endocarditis, or rejected infective endocarditis.[42]

TABLE 134-14

Diagnosis of Infective Endocarditis According to the Modified Duke Criteria

Definite IE
Pathological criteria Microorganisms demonstrated by culture or histological examination of a vegetation, a vegetation that has embolized, or an intracardiac abscess specimen; or pathological lesions; vegetation or intracardiac abscess confirmed by histological examination showing active endocarditis Clinical criteria Two major criteria, or One major criteria and three minor criteria, or Five minor criteria
Possible IE
One major criterion and one minor criteria, or Three minor criteria
Rejected IE
Firm alternative diagnosis explaining evidence of infective endocarditis, or Resolution of infective endocarditis syndrome with antimicrobial therapy for four or fewer days, or No pathological evidence of infective endocarditis at surgery or autopsy, with antimicrobial therapy for 4 or fewer days, or does not meet criteria for possible infective endocarditis, as above
Major Criteria
Blood culture positive for infective endocarditis Typical microorganisms consistent with infective endocarditis from 2 separate blood cultures: Viridans streptococci, *S. gallolyticus*, HACEK group, *S. aureus*; or Community-acquired enterococci, in the absence of a primary focus; or Microorganisms consistent with infective endocarditis from persistently positive blood cultures, defined as follows: At least two positive blood cultures drawn greater than 12 hours apart; or Three or a majority of 4 or more separate blood cultures (with first and last sample drawn at least 1 hr apart) Single positive blood culture for *Coxiella* burnetii or antiphase I immunoglobulin G antibody titer >1:800
Evidence of endocardial involvement Echocardiogram positive for infective endocarditis (transesophageal echocardiography recommended for patients with prosthetic valves, rated at least "possible infective endocarditis" by clinical criteria, or complicated infective endocarditis [paravalvular abscess]; transthoracic echocardiography as first test for other patients), defined as follows:

Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets or on implanted material in the absence of an alternative anatomic explanation; or abscess; or New partial dehiscence of prosthetic valve New valvular regurgitation (worsening or changing of preexisting murmur not sufficient)
Minor Criteria
Predisposition, predisposing heart condition, or injection drug use Fever, temperature >38°C (100.4°F) Vascular phenomena, major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjuncti val hemorrhages, and Janeway lesions Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth's spots, and rheumatoid factor Microbiologic evidence: positive blood culture but does not meet a major criterion as noted above or serologic evidence of active infection with organism consistent with infective endocarditis Echocardiographic minor criteria eliminated

HACEK, Haemophilus species (*H. parainfluenzae, H. aphrophilus, H. paraphrophilus*), Aggregatibacter species, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*.

Data from References 41,42.

The hallmark of infective endocarditis is a continuous bacteremia caused by bacteria shedding from the vegetation into the bloodstream; 90% to 95% of patients with infective endocarditis have positive blood cultures.[2,5,23,43] In most cases, three sets of blood cultures, should be collected prior to starting antimicrobial therapy, with the first and last set drawn at least 1 hourapart. This allows expedient initiation of empirical antimicrobial therapy and can help guide early decisions regarding other potential interventions. Most cases of infective endocarditis are caused by easily cultivable pathogens that can be isolated from routine blood cultures within a 5-day incubation period. However, prolonged incubation of blood cultures or specialized testing may need to be performed (see "'culture-negative' infective endocarditis" below). In patients who undergo valve surgery, excised valve tissue should be submitted for microbiologic testing. Additionally, histopathologic evaluation should be performed to identify the presence of microorganisms and characteristics of inflammatory changes. Specialized testing (eg, polymerase chain reaction [PCR]) may also be performed on valve tissue to improve the likelihood of identifying the infectious etiology.

"Culture-negative" infective endocarditis describes a patient in whom a clinical diagnosis of infective endocarditis is likely, but blood cultures do not yield a pathogen. This condition is often the consequence of previous antimicrobial therapy, improperly collected blood cultures, or unusual organisms.[5] When blood cultures from patients suspected of having infective endocarditis do not grow after 48 to 72 hours, cultures should be held for up to a month to detect growth of fastidious organisms.[5] Specialized testing, such as serology or PCR, may be required to identify less common pathogens (eg, *Coxiella burnetii*, *Bartonella* spp., *Brucella* spp.).

An electrocardiogram, chest radiograph or computed tomography, and echocardiogram are performed for patients suspected of endocarditis. The electrocardiogram rarely shows important diagnostic findings but may reveal heart block, suggesting extension of the infection. The chest radiograph or computed tomography may provide more diagnostic information, such as identification of septic pulmonary emboli in a patient with right-sided endocarditis. Septic pulmonary emboli may occur, leading to multiple lung foci.

Echocardiography plays an important role in the diagnosis and management of infective endocarditis and should be performed for all patients suspected of this infection.[5,6] In addition to helping in the diagnosis of infective endocarditis, the echocardiogram allows the clinician to evaluate hemodynamic stability and the need for urgent surgical intervention; it also provides a rough estimate of the likelihood of embolism.[5] Typically, transthoracic echocardiography (TTE) is performed first due to the rapidity (eg, fasting state unnecessary) and accessibility (eg, 24-hour service available in most institutions) followed by transesophageal echocardiography (TEE). TEE is more sensitive for detecting vegetations (90%-100%) as compared with TTE (40%-66%), and TEE maintains good specificity (90%-100%).[2,6,19] However, TTE may be the only evaluation needed for children or adults in whom the clinical suspicion of infective endocarditis is relatively low.[5,43] An initial or follow-up TEE is recommended in high-risk patients such as those with CHD, previous endocarditis, new murmur, heart failure, or other stigmata of endocarditis.[5,28] For those patients with suspected PVE or CDIE, TEE should be considered mandatory. The lack of vegetation on echocardiogram does not exclude infection even if the transesophageal approach is used. In these cases, there is an evolving role for advanced imaging modalities such as three dimensional TEE, 18-F fluorodeoxyglucose (FDG) positron emission tomographic/computed tomographic (PET/CT), and single-photon emission computed tomography.[5,6]

TREATMENT

TABLE 134-5

Treatment Options for Native Valve Endocarditis by Causative Organism

Agent[a]	Duration	Strength of Recommendation	Comments
Highly Penicillin-Susceptible (MIC ≤ 0.12 μg/mL [mg/L]) Viridans Group Streptococci and *S. gallolyticus*			
Aqueous crystalline penicillin G sodium[b]	4 weeks	IIaB	2-week regimens are not intended for the following patients: ○ Most patients >65 years of age ○ Children ○ Impairment of the eighth cranial nerve function ○ Renal function with a creatinine clearance <20 mL/min (<0.33 mL/s) ○ Known cardiac or extracardiac abscess ○ Infection with *Abiotrophia, Granulicatella*, or *Gemalla* species
Ceftriaxone	4 weeks	IIaB	
Aqueous crystalline penicillin G sodium[b] plus gentamicin	2 weeks	IIaB	
Ceftriaxone plus gentamicin	2 weeks	IIaB	
Vancomycin	4 weeks	IIaB	Recommended only for patients unable to tolerate penicillin or ceftriaxone
Viridans Group Streptococci and *S. gallolyticus* Relatively Resistant to Penicillin (MIC >0.12 to ≤0.5 μg/mL [mg/L])			
Aqueous crystalline penicillin G sodium[b] plus gentamicin	4 weeks 2 weeks	IIaB	
Ceftriaxone plus gentamicin	4 weeks 2 weeks	IIbC	
Vancomycin	4 weeks	IIaB	Recommended only for patients unable to tolerate penicillin or ceftriaxone
Oxacillin-Susceptible Staphylococci[c]			
Nafcillin or oxacillin	6 weeks	IC	
Cefazolin	6 weeks	IB	For use in patients with non-anaphylactoid-type penicillin allergies; patients with an unclear history of immediate-type hypersensitivity to penicillin should be considered for skin testing
Vancomycin	6 weeks	IB	For use in patients with anaphylactoid-type hypersensitivity to penicillin and/or cephalosporins
Daptomycin	6 weeks	IIaB	For use in patients with immediate-type hypersensitivity reactions to penicillin
Oxacillin-Resistant Staphylococci			
Vancomycin	6 weeks	IC	
Daptomycin	6 weeks	IIbB	

[a] See Tables 134-9 and 134-10 for appropriate dosing, administration, and monitoring information.

[b] May use ampicillin in the event of a penicillin shortage.

[c] Regimens indicate treatment for left-sided endocarditis or complicated right-sided endocarditis; uncomplicated right-sided endocarditis may be treated for shorter durations and is described in the text. Please refer Table 134-7 for treatment of NVE caused by enterococci.

Data from References 5,6.

TABLE 134-6

Treatment Options for Prosthetic Valve Endocarditis (PVE) by Causative Organism

Agent[a]	Duration	Strength of Recommendation	Comments
Highly Penicillin-Susceptible (MIC ≤ 0.12 μg/mL [mg/L]) Viridans Group Streptococci and *S. gallolyticus*			
Aqueous crystalline penicillin G sodium[b] plus gentamicin	6 weeks 2 weeks	IIaB	Combination therapy with gentamicin has not demonstrated superior cure rates compared with monotherapy with a penicillin or cephalosporin and should be avoided in patients with CrCl <30 mL/min (<0.50 mL/s)
Ceftriaxone plus gentamicin	6 weeks 2 weeks	IIaB	
Vancomycin	6 weeks	IIaB	Recommended only for patients unable to tolerate penicillin or ceftriaxone
Relatively Resistant or Fully Resistant (MIC > 0.12 μg/mL [mg/L]) Viridans Group Streptococci and *S. gallolyticus*			
Aqueous crystalline penicillin G sodium[b] plus gentamicin	6 weeks	IIaB	
Ceftriaxone plus gentamicin	6 weeks	IIaB	
Vancomycin[c]	6 weeks	IIaB	Recommended only for patients unable to tolerate penicillin or ceftriaxone
Oxacillin-Susceptible Staphylococci			
Nafcillin or oxacillin	≥6 weeks	IB	Cefazolin may be substituted for nafcillin or oxacillin in patients with non-immediate-type hypersensitivity
plus rifampin	≥6 weeks		
plus gentamicin	2 weeks		
Vancomycin	≥6 weeks	IB	Recommended only for patients with anaphylactoid-type hypersensitivity to penicillin and/or cephalosporins
plus rifampin	≥6 weeks		
plus gentamicin	2 weeks		
Oxacillin-Resistant Staphylococci			
Vancomycin	≥6 weeks	IB	
plus rifampin	≥6 weeks		
plus gentamicin	2 weeks		

[a] See Tables 134-9 and 134-10 for appropriate dosing, administration, and monitoring information.

[b] May use ampicillin in the event of a penicillin shortage.

[c] The ESC 2015 guidelines recommend gentamicin (3 mg/kg/day) be administered with vancomycin for the initial 2 weeks of therapy in patients with relatively resistant strains to penicillin.

PVE, prosthetic valve endocarditis; MIC, minimum inhibitory concentration.

Please refer Table 134-3 for treatment of PVE caused by enterococci.

Data from References 5,6.

TABLE 134-7

Treatment Options for Native or Prosthetic Valve Endocarditis Caused by Enterococci

Agent[a]	Duration[b]	Strength of Recommendation	Comments
Ampicillin-, Penicillin-, and Vancomycin-Susceptible Strains			
Ampicillin plus gentamicin	4-6 weeks	IIaB	Native valve plus symptoms present for <3 months: use 4-week regimen
Aqueous crystalline penicillin G sodium plus gentamicin	4-6 weeks	IIaB	Prosthetic valve or native valve plus symptoms present for >3 months: use 6-week regimen
Ampicillin plus ceftriaxone	6 weeks	IIaB	Recommended regimen if creatinine clearance is <50 mL/min (<0.83 mL/s; at baseline or due to therapy with a gentamicin-containing regimen)
Vancomycin plus gentamicin	6 weeks	IIaB	Recommended only for patients unable to tolerate penicillin or ampicillin
Gentamicin-Resistant Strains			
If susceptible, use streptomycin in the place of gentamicin in the regimens listed above if creatinine clearance is >50 mL/min (>0.83 mL/s), cranial nerve VIII function is intact and there is laboratory capability for rapid streptomycin serum concentrations.			
Penicillin-Resistant Strains			
Ampicillin–sulbactam plus gentamicin (β-lactamase–producing strain)	6 weeks	IIbC	
Vancomycin plus gentamicin (intrinsic penicillin resistance[c])	6 weeks	IIbC	May also be used in patients with β-lactamase–producing strains who have known intolerance to ampicillin–sulbactam
Enterococcus Faecium **Strains Resistant to Penicillin, Aminoglycosides, and Vancomycin[d]**			
Linezolid	>6 weeks	IIbC	Antimicrobial cure rates may be <50%; bacteriologic cure may only be achieved with cardiac valve replacement
Daptomycin	>6 weeks	IIbC	

[a] See Tables 134-9 and 134-10 for appropriate dosing, administration, and monitoring information.

[b] All patients with prosthetic valves should be treated for at least 6 weeks.

[c] Infectious diseases consult highly recommended.

[d] Patients should be managed by a multidisciplinary team that includes specialists in cardiology, cardiovascular surgery, infectious diseases, and clinical pharmacy.

Data from Reference 5.

TABLE 134-8

Treatment Options for Culture-Negative Endocarditis and Endocarditis Caused by Gram-Negative Organisms[a]

Agent[b]	Duration[c]	Strength of Recommendation	Comments
HACEK[d] Microorganisms			
Ceftriaxone	4 weeks	IIaB	Other third- or fourth-generation cephalosporins may be used as an alternative
Ampicillin or Ampicillin–sulbactam	4 weeks	IIaB	Should only use if growth is adequate for in vitro susceptibility testing; otherwise, consider organism to be resistant
Ciprofloxacin	4 weeks	IIbC	Recommended for patients with known intolerance to cephalosporins or ampicillin; other fluoroquinolones may be used as an alternative
Culture-Negative Endocarditis, Native Valve[e]			
Vancomycin plus cefepime	4-6 weeks	IIaC	Recommended when onset is acute (days); *S. aureus*, β-hemolytic streptococci, and aerobic gram-negative bacilli should be covered
Vancomycin plus ampicillin–sulbactam	4-6 weeks	IIaC	Recommended when onset is subacute (weeks); *S. aureus*, viridans group streptococci, HACEK, and enterococci should be covered
Culture-Negative Endocarditis, Early (<1 Year) Prosthetic Valve[e]			
Vancomycin plus cefepime plus rifampin plus gentamicin	6 weeks	IIaC	Staphylococci, enterococci, and aerobic gram-negative bacilli should be covered
Culture-Negative Endocarditis, Late (>1 Year) Prosthetic Valve[e]			
Vancomycin plus ceftriaxone	6 weeks	IIaC	Staphylococci, viridans group streptococci, and enterococci should be covered
Suspected *Bartonella*, Culture-Negative			
Ceftriaxone	6 weeks	IIaB	
plus gentamicin	2 weeks		
with or without doxycycline	6 weeks		
Culture-Positive *Bartonella*			
Doxycycline plus gentamicin	6 weeks 2 weeks	IIaB	Rifampin is recommended as an alternative in patient who cannot be given gentamicin

[a] Infectious disease consult highly recommended.

[b] See Tables 134-9 and 134-10 for appropriate dosing, administration, and monitoring.

[c] All patients with prosthetic valves should be treated for 6 weeks.

[d] *Haemophilus* species (*H. parainfluenzae, H. aphrophilus*, and *H. paraphrophilus*), *Aggregatibacter* species, *Cardiobacterium hominis, Eikenella corrodens*, and *Kingella kingae.*

[e] Duration of therapy for culture-negative endocarditis may be variable and should be based on clinical course and recommendations from infectious diseases consult.

Data from References 5,6.

TABLE 134-9

Drug Dosing Table for Treatment of Infective Endocarditis[a]

Drug	Brand Name	Recommended Dose	Pediatric (Ped) Dose[b]	Additional Information
Ampicillin	NA	2 g IV every 4 hr	50 mg/kg every 4 hr or 75 mg/kg every 6 hr	24-hr total dose may be administered as a continuous infusion: 12 g IV every 24 hr
Ampicillin–sulbactam	Unasyn®	3 g IV every 6 hr	50 mg/kg every 4 hr or 75 mg/kg every 6 hr	
Aqueous crystalline penicillin G sodium	NA			
• MIC <0.12 μg/mL (mg/L) (native valve only)		3 million units IV every 4 hr or every 6 hr	50,000 units/kg IV every 6 hr	24-hr total dose may be administered as a continuous infusion: 12-18 million units IV every 24 hr (Ped: 200,000 units/kg IV/24 hours)
• All other indications		4 million units IV every 4 hr or 6 million units IV every 6 hr	50,000 units/kg IV every 4 hr or 75,000 units/kg IV every 6 hr	24 million units IV every 24 hr (Ped: 300,000 units/kg IV every 24 hr)
Cefazolin	N/A	2 g IV every 8 hr	33 mg/kg IV every 8 hr	
Cefepime	Maxipime®	2 g IV every 8 hrr	50 mg/kg IV every 8 hr	
Ceftriaxone sodium	N/A	2 g IV or IM every 24 hr 2 g IV or IM every	100 mg/kg IV or IM every 24 hr	

		12 hr		
Ciprofloxacin	Cipro®	400 mg IV every 12 hr or 500 mg po every 12 hr	20-30 mg/kg IV or po every 12 hr	Avoid use if possible in patients <18 years of age
Daptomycin	Cubicin®	≥8 mg/kg IV every 24 hr	6 mg/kg IV every 24 hr	Doses as high as 10-12 mg/kg IV every 24 hr have been used in adults with enterococcus resistant to penicillin, aminoglycosides and vancomycin; doses should be calculated using actual body weight
Doxycycline	Vibramycin®	100 mg IV or po every 12 hr	1-2 mg/kg IV or po every 12 hr	
Gentamicin sulfate	NA	3 mg/kg IV or IM every 24 hr or 1 mg/kg IV or IM every 8 hr[c]	1 mg/kg IV or IM every 8 hr	Once-daily dosing is only recommended for treatment of streptococcal infections.
Linezolid	Zyvox®	600 mg IV or po every 12 hr	10 mg/kg IV every 8 hr	
Nafcillin or oxacillin	NA	2 g IV every 4 hr	50 mg/kg IV every 6 hr	
Rifampin	Rifadin®	300 mg IV or po every 8 hr	5-7 mg/kg IV or po every 8 hr	
Streptomycin	NA	7.5 mg/kg IV or IM every 12 hr		
Vancomycin	Vancocin®	15-20 mg/kg IV every 8 hours or every 12 hr	15 mg/kg IV every 6 hr	A loading dose of 25-30 mg/kg may be administered in adults; doses should be calculated using actual body weight; single doses should not exceed 2 g

[a] All doses assume normal renal function.

[b] Should not exceed adult dosage.

[c] Actual body weight should be used when the full aminoglycoside dose is administered once daily; when administered in three divided doses, use ideal body weight or adjusted body weight when actual body weight is >120% ideal body weight.

Desired Outcomes

The desired outcomes for treatment of bacteremias are to:

1. Eradicate the causative organism with optimal therapy while minimizing therapeutic failure and potential for resistance
2. Identify and manage the focal (primary) source of infection as well as any secondary foci (metastatic) of infections
3. Relieve the signs and symptoms associated with the infection including the bacteremia, primary source of infection, and if present, secondary

metastatic infections

4. Decrease morbidity and mortality associated with the bacteremia and primary source of infection
5. Provide cost-effective antimicrobial therapy determined by the likely or identified pathogen, drug susceptibilities, hepatic and renal function, drug allergies, and anticipated drug toxicities

The desired outcomes for treatment and prophylaxis of infective endocarditis are to:

1. Relieve the signs and symptoms of the disease
2. Decrease morbidity and mortality associated with the infection
3. Eradicate the causative organism with minimal drug exposure
4. Provide cost-effective antimicrobial therapy determined by the likely or identified pathogen, drug susceptibilities, hepatic and renal function, drug allergies, and anticipated drug toxicities
5. Prevent infective endocarditis from occurring or recurring in high-risk patients with appropriate prophylactic antimicrobials

General Approach to Treatment

Bacteremia

7 Urgent initiation of appropriate antibacterial therapy is necessary in patients with bacteremia as delays are associated with increased morbidity and mortality.[44] Empirical parenteral therapy should be based on the usual pathogens at the site(s) of presumptive primary source(s) of infection. In the case of an unknown primary source of infection or primary bacteremia (those without an obvious source), selection of empirical parenteral antibacterial therapy is more challenging but should provide a broad spectrum of activity while additional diagnostic testing is performed to determine the site(s) of infection. Source control (eg, drainage, debridement) may be required depending on the primary source(s) or secondary metastatic of infections (eg, intra-abdominal infections [Chapter 137], bone and joint infections [Chapter 141]). Additional (double) coverage is unnecessary if the empirical therapy is likely to have activity against the potential pathogens but may prove beneficial if patient-specific risk factors for antimicrobial resistance are present or local resistance rates are high based on antibiogram data (Chapter e126).

Once microbiologic data from blood cultures are available, findings should then be interpreted to differentiate contamination from true bacteremia (Table 134-3) in conjunction with the patient's clinical history, physical findings, risk factors (Table 134-1), and diagnostic testing. However, if the significance of blood culture findings or antimicrobial selection is uncertain, consultation with an infectious diseases specialist should be performed.[44] Antibacterial therapy should be deescalated to target that specific pathogen based on microbiologic data including Gram's stain results from rapid diagnostic testing and antimicrobial susceptibility testing data. Though no general guideline exists for bacteremia, management often depends on the specific organism(s) identified, as well as primary source(s) or secondary metastatic infections to determine the appropriate non-pharmacological and pharmacological treatments. In most cases, treatment is initiated in the hospital, but can often be completed in the outpatient setting (termed outpatient antimicrobial therapy [OPAT]) once source control has been achieved and the patient has clinically improved. Patients considered for OPAT must be hemodynamically stable, compliant with therapy, have careful medical monitoring, understand the potential complications of the disease, and have immediate access to medical care. Advances in technology allow for the outpatient administration of complex antimicrobial regimens that significantly reduce the cost of therapy. Simple regimens, such as single daily doses of ceftriaxone or continuous infusions of penicillin, may improve patient convenience and potentially compliance. Although bacteremia and infective endocarditis are common in PWID and home healthcare would substantially reduce the cost of treatment, many clinicians are hesitant with outpatient IV therapy because central venous access is required. However, there are no significant differences in rates of vascular access complications between those who do and do not inject drugs.[45] Parenteral antibacterial therapy has been considered the standard of care, but emerging data support the use of oral antibacterial therapy in select patients.[46]

Infective Endocarditis

Empirical antimicrobial therapy should usually be initiated in most patients after presumptive or confirmed diagnosis of infective endocarditis.[5] However, in select patients, who are not acutely ill, empiric antimicrobial therapy can be withheld until the results of blood or tissue cultures or serologic tests are available. Due to the importance of identifying an infectious etiology, antimicrobial therapy should not be started until blood cultures have been obtained. Patient history, including past medical, surgical, social, and family, risk factors, and current and previous antimicrobial therapy should be considered when selecting empirical antimicrobial therapy. Consultation with an infectious diseases specialist should occur to assist in selecting an optimal empirical therapy.

Specific treatment recommendations from the American Heart Association (AHA) and the European Society of Cardiology (ESC) provide guidance for the management of infective endocarditis.[5] Both provide important recommendations for the combination of early diagnosis, early antimicrobial therapy, and early surgery; but there are some subtle differences. The ESC guidelines recommend that an "endocarditis team," consisting of cardiologists, cardiac surgeons, and specialists in infectious diseases, manage patients with infective endocarditis. The AHA guidelines place more emphasis on a team-based approach when assessing the timing and need for surgical intervention.

The AHA and ESC guidelines use an evidence-based scoring system where recommendations are given a classification as well as level of evidence. Class I recommendations are conditions for which there is evidence, general agreement, or both that a given procedure or treatment is useful and effective. Class II recommendations are conditions for which there is conflicting evidence, a divergence of opinion, or both about the usefulness/efficacy of a procedure or treatment (IIa implies that the weight of evidence/opinion is in favor of usefulness/efficacy, whereas IIb implies that usefulness/efficacy is less well established by evidence/opinion). Class III recommendations are conditions for which there is evidence, general agreement, or both that the procedure/treatment is not useful/effective and in some cases may be harmful. Level of evidence is listed as A (data derived from multiple randomized clinical trials), B (data derived from a single randomized trial or non-randomized studies), and C (consensus opinion of experts).

⑧ The most important approach in the treatment of infective endocarditis is isolation of the infecting pathogen and determination of antimicrobial susceptibilities, followed by high-dose, antimicrobial therapy, most often administered via parenteral route, for an extended period.[5–7,32] Susceptibility testing is crucial given the increasing rate of antimicrobial resistance to commonly encountered pathogens. Treatment usually is started in the hospital, but for select patients it is often completed in the outpatient setting (OPAT). Large doses of parenteral antimicrobials, as opposed to oral antimicrobials, are recommended to achieve bactericidal concentrations within vegetations. An extended duration of therapy is required, even for susceptible pathogens, because microorganisms are enclosed within valvular vegetations and fibrin deposits. These barriers impair host defenses and protect microbes from phagocytic cells. In addition, high bacterial concentrations within vegetations may result in an inoculum effect that further resists killing (see Chapter e126 for additional discussion). Many bacteria are not actively dividing, further limiting the rate of bacterial death. For most patients, a minimum of 4 to 6 weeks of therapy is required.[5,6]

In the Partial Oral Treatment of Endocarditis (POET) trial, changing to oral antimicrobial therapy after at least 10 days of IV therapy was non-inferior to continuing IV antimicrobial therapy in patients with left-sided native or PVE caused by streptococci, *Enterococcus faecalis*, *S. aureus* (not MRSA), or coagulase-negative staphylococci.[47] All-cause mortality, unplanned cardiac surgery, embolic events, or relapse of bacteremia within 6 months, was similar between groups. Oral regimens included a combination of at least two of the following antimicrobials: moxifloxacin, amoxicillin, clindamycin, rifampicin, dicloxacillin, fusidic acid, and linezolid. Due to strict inclusion and exclusion criteria, frequent outpatient follow-up required, and use of oral antimicrobial agents that are unavailable or infrequently used in the United States, only a select group of patients with left-sided infective endocarditis with functioning GI tracts and a high likelihood for compliance may be candidates for combination oral antimicrobial therapy.

Non-pharmacologic Therapy

Bacteremia

① Management of bacteremia requires identification and resolution of primary source(s) of infection via source control which is defined as a physical intervention aimed at removing or eliminating a focus of invasive infection (Table 134-4) and most often performed by a surgeon.[48] Source control may include one or more of the following: drainage, debridement, device removal, and definitive reconstructive manners. The ability to successfully complete source control depends on whether an anatomic diagnosis can be established and if the patient is stable enough to undergo the procedure(s).

In addition, echocardiography, a component of the Modified Duke Criteria, is frequently performed in patients with bacteremia, especially in those with suspected infective endocarditis. Though less clear for other causes of bacteremia, echocardiography should be performed in all patients with *S. aureus* bacteremia as the prevalence of infective endocarditis is approximately 25%.[49] However, significant variation exists as to which patients should undergo TEE following an unremarkable TTE. While TEE is preferred due to increased sensitivity, TTE may be sufficient in select patients without specific risk factors for infective endocarditis, such as those with nosocomial acquisition without intracardiac devices or dependence on hemodialysis.

Due to the high morbidity and mortality associated with bacteremia, evidence-based practices that include appropriate selection and duration of antimicrobial therapy, in addition to diagnostic testing to identify the primary source(s) or secondary metastatic infection(s), as well as infective endocarditis, are crucial. Unfortunately, these recommendations do not always translate into clinical practice. Consultation with infectious diseases providers to ensure adherence to these evidence-based practices, especially in patients with *S. aureus* or *Enterococcus* spp. bacteremia, has been associated with decreased risk of recurrence, fewer readmissions, and lower mortality rates.[50–53] Since consultation with infectious diseases providers may not be feasible in all healthcare settings, automated pharmacist and/or antimicrobial stewardship program interventions have been developed to increase adherence to evidence-based practices.[54]

Infective Endocarditis

Surgical intervention to remove the infectious foci and repair valves and/or valvular structures is an important adjunct in the management of both NVE and PVE and is now performed in up to 50% of patients.[21] In most surgical cases, valvectomy and valve replacement are performed to remove infected tissue and to restore hemodynamic function. Indications for surgery include heart failure, persistent bacteremia, persistent vegetation, an increase in vegetation size, or recurrent emboli despite prolonged antimicrobial treatment, valve dysfunction, paravalvular extension (eg, abscess), or endocarditis caused by difficult to treat or resistant organisms (eg, fungi or gram-negative bacteria).[5–7] More controversial is the appropriate timing of surgery as well as duration of antimicrobial therapy postoperatively. Additionally, studies evaluating postsurgical outcomes and associated mortality are limited such that a specific risk prediction system has not been established.[55–59] Early surgery (eg, within 48 hr) may be appropriate in patients with severe heart failure and large vegetations, whereas patients with septic shock, advanced age, or neurologic complications of infective endocarditis may have more detrimental outcomes.[55,57,60,61] The multiple factors that need to be considered in evaluating the need for and timing of surgery is why a multidisciplinary management approach (eg, "endocarditis team") is critical.[5,6,32]

Pharmacologic Therapy

Bacteremia

Gram-Negative Bacilli

Detection of gram-negative bacilli from blood cultures should always be considered significant and prompt initiation of empirical parenteral therapy based on the patient's history, comorbidities, previous microbiologic results, as well as whether the infection is community- or healthcare-acquired and local resistance patterns. Ceftriaxone, cefepime, or piperacillin/tazobactam should be added in cases where *P. aeruginosa* is an unlikely pathogen. While an anti-pseudomonal carbapenem (eg, meropenem) should be active, these broad-spectrum antibacterial agents are typically reserved for patients with a history of drug-resistant gram-negative organisms. The risks for *P. aeruginosa* bacteremia include hospital-onset gram-negative bacteremia, as well as healthcare exposures, hemodialysis, residence in a long-term care facility, recent antibacterial or chemotherapy treatment, or immunodeficiency. If *P. aeruginosa* is a concern (eg, hospital-onset gram-negative bacteremia), a single agent consisting of an anti-pseudomonal cephalosporin, anti-pseudomonal β-lactam/β-lactamase inhibitor (eg, piperacillin/tazobactam), or anti-pseudomonal carbapenem (eg, meropenem), is appropriate in patients where less than 10% to 20% of *P. aeruginosa* isolates are resistant to the empiric therapy. Alternatively, double coverage consisting of an anti-pseudomonal cephalosporin (eg, ceftazidime, cefepime), anti-pseudomonal β-lactam/β-lactamase inhibitor (eg, piperacillin/tazobactam), or anti-pseudomonal carbapenem (eg, meropenem) combined with an aminoglycoside or anti-pseudomonal fluoroquinolone should be considered in patients with immunodeficiencies or risk factors for drug-resistant *P. aeruginosa* hospitalized at a facility where more than 10% to 20% of *P. aeruginosa* isolates are resistant to the empiric therapy.[62] Empiric antibacterial therapy against multidrug-resistant organisms (eg, extended spectrum β-lactamase [ESBL]- or carbapenemase-producing Enterobacterales) is warranted in patients with a history of infection(s) caused multidrug-resistant organisms, areas with high local prevalence of multidrug-resistant organisms, and cases of breakthrough bacteremia in patients receiving antibacterial therapy for gram-negative organisms.

Once identification and susceptibility results are available, antibacterial therapy should be deescalated to the most narrow spectrum agent to target the specific pathogen(s) isolated and avoid unnecessary adverse events and inducing resistance.[62] Parenteral therapy has been considered the standard of care for gram-negative bacilli bacteremia. Many oral antimicrobial agents are highly bioavailable and provide therapeutic concentrations within the bloodstream and at the primary source of infection, which may achieve similar outcomes to patients treated exclusively with parenteral antimicrobial therapy, especially in patients with uncomplicated gram-negative bacteremia defined as no evidence of central nervous system, cardiovascular, osteoarticular, or other deep-seated infection.[63]

Similar 30-day mortality was observed in patients with uncomplicated Enterobacterales bacteremia from a urinary, intra-abdominal, vascular catheter, pulmonary, or skin and soft tissue source who switched to an oral antibacterial agent after a median 3 days of parenteral therapy compared to those who continued parenteral therapy for the entire duration.[46] The majority of patients in the oral therapy group were changed to a fluoroquinolone or trimethoprim/sulfamethoxazole, while the remainder received oral β-lactams. Oral β-lactams have not been frequently used for patients with uncomplicated Enterobacterales bacteremia due to limited bioavailability and variable bloodstream concentrations.[63] However, 30-day recurrent bacteremia and 30-day mortality were not significantly different with oral β-lactams compared with oral fluoroquinolones or trimethoprim/sulfamethoxazole among patients with *E. coli*, *Klebsiella* spp., or *Proteus* spp. bacteremia from a urinary source.[64] Patients were transitioned to oral fluoroquinolones or trimethoprim/sulfamethoxazole after a median 5 days of parenteral therapy compared to 4 days for those receiving oral β-lactams, which consisted of amoxicillin/clavulanate, cephalexin, and cefpodoxime proxetil. In most cases, patients with uncomplicated Enterobacterales bacteremia may be safely transitioned to oral antibacterial therapy after approximately 3 days of parenteral therapy. Selection of oral antibacterial therapy with high bioavailability and optimal dosing are necessary to ensure therapeutic concentrations within the bloodstream and at the primary source of infection.[65] However, parenteral therapy should be administered for the entire duration in cases where those criteria cannot be satisfied.

Traditionally, patients with uncomplicated gram-negative bacteremia received 14 days of parenteral antibacterial therapy, but treatment durations can be shortened to 7 days in most patients. A randomized trial comparing 7 to 14 days of antibacterial therapy in patients with uncomplicated gram-negative bacteremia found no significant differences in 14- or 28-day mortality between groups.[66] Additionally, a 9-day duration of antimicrobial therapy and a 16-day duration for uncomplicated *P. aeruginosa* bacteremia resulted in similar rates of recurrent infection or mortality within 30 days of antimicrobial cessation.[30]

Gram Positive

Staphylococcus aureus

Empirical therapy in patients with suspected *S. aureus* bacteremia, prior to susceptibility results, should include activity against MRSA with either vancomycin or daptomycin in the majority of cases due to the increased rate of MRSA identified in hospital- and community-acquired bacteremias.[49] If the isolate is later identified as MSSA, therapy should be deescalated to an antistaphylococcal or penicillinase-resistant penicillin (eg, nafcillin, oxacillin) or cephalosporin (eg, cefazolin) as vancomycin is less effective than β-lactams against MSSA.[67] Though cefazolin may be considered in patients who report a hypersensitivity to penicillin not associated with anaphylactic features, treatment should be dictated by allergy history or skin testing. Alternatively, vancomycin or daptomycin (a respiratory source of bacteremia should be ruled out prior to starting daptomycin) should be administered to those unable to tolerate β-lactams. Vancomycin and daptomycin are considered first-line treatment of MRSA bacteremia. Though time to blood culture sterilization may be decreased with combination therapy compared to single-drug therapy, rates of morbidity and mortality remain unchanged.

Management of some patients with MRSA bacteremia may be complicated by persistent bacteremia, defined as inability to sterilize blood cultures after 3 to 7 days of active therapy.[68,69] Persistent *S. aureus* bacteremia is associated with higher rates of secondary metastatic infections and death and may warrant the use of salvage therapy consisting of daptomycin 8 to 10 mg/kg combined with a β-lactam such as ceftaroline.[70]

Establishing a duration of therapy requires differentiation of patients with uncomplicated or low-risk and complicated or high-risk *S. aureus* bacteremia.[49,68] To meet criteria for uncomplicated or low-risk *S. aureus* bacteremia, all of the following criteria must be met: 1) sterile repeat blood cultures 48 to 96 hours after the initial positive culture, 2) defervescence within 72 hr after initiation of active therapy, 3) exclusion of infective endocarditis/secondary metastatic infection, 4) no implanted prostheses (eg, prosthetic valves, cardiac devices, or arthroplasties), 5) not dependent on hemodialysis. Patients with uncomplicated *S. aureus* bacteremia require treatment for 2 weeks, whereas those with complicated *S. aureus* bacteremia should be treated for 4 to 6 weeks from the first negative blood culture or source control. Differentiating uncomplicated *S. aureus* bacteremia from complicated *S. aureus* bacteremia is challenging as almost 33% of patients initially classified as having uncomplicated *S. aureus* bacteremia were eventually diagnosed with complicated *S. aureus* bacteremia.[71] As a result, the majority of patients should receive 4 to 6 weeks of treatment. Parenteral therapy is considered standard of care in patients with uncomplicated and complicated *S. aureus* bacteremia, but successful use of oral therapies has been reported in patients with or uncomplicated *S. aureus* bacteremia.[72]

Coagulase negative Staphylococcus spp.

IV vancomycin should be started empirically in patients with suspected coagulase negative *Staphylococcus* spp. bacteremia due to high rates of methicillin resistance.[73] As with management of *S. aureus* bacteremia, an antistaphylococcal or penicillinase-resistant penicillin (eg, nafcillin, oxacillin) or cephalosporin (eg, cefazolin) should be administered if the isolate is methicillin susceptible, whereas vancomycin or daptomycin should be reserved for those infected with methicillin-resistant strains. Treatment duration varies, depending on catheter removal, from 5 to 7 days in patients with negative follow-up blood cultures, no evidence of secondary metastatic infection, and no intravascular prostheses to 7 to 14 days in patients with at least two positive blood cultures obtained more than 24 hours apart or intravascular prostheses.[74] However, treatment of *S. lugdunensis* bacteremia should be managed in a similar manner to that of *S. aureus* bacteremia due to similarities in virulence.

Streptococcus spp.

β-Lactams remain first-line therapy for streptococcal bacteremias. However, combination empirical therapy with IV vancomycin and ceftriaxone should administered in patients with suspected *S. pneumoniae* bacteremia, pending susceptibilities, until central nervous system involvement can be ruled out. For empirical treatment of Group A streptococcal (*S. pyogenes*) bacteremia, IV penicillin should be combined with IV clindamycin to suppress toxin production, as well as decrease the risk of treatment failure and death.[75] IV clindamycin can be discontinued after 48 hr in patients without shock, organ failure, or necrotizing fasciitis. In most cases of streptococcal bacteremia, monotherapy with IV penicillin or ceftriaxone is appropriate once susceptibility results are available, although it is unclear if parenteral therapy is required for the entire duration of treatment.[76] Antibacterial therapy is typically administered for 14 days, but limited data are available evaluating optimal treatment duration.

Enterococcus spp.

Enterococcus spp. are usually of low virulence but inherently resistant to many classes of antibacterial agents.[5] *E. faecalis* is the most common clinical isolate (approximately 97%) of the two species.[74,77] Penicillins and glycopeptides are most active despite their inability to consistently kill these organisms. Ampicillin has greater in vitro activity than penicillin, although there are no clinical data to document differences in efficacy. IV ampicillin should be administered when the isolate is susceptible in non-critically ill patients with no evidence of infective endocarditis. Alternatively, IV vancomycin can be administered in patients who report hypersensitivity to penicillin and are unable to be desensitizied. Ampicillin-resistant, vancomycin-susceptible isolates can be treated with IV vancomycin or daptomycin. The incidence of vancomycin-resistant enterococci (VRE), primarily with *E. faecium*, is increasing. Vancomycin resistance occurs when the bacterium replaces the normal vancomycin target with a peptidoglycan precursor that does not bind vancomycin.[78] In cases of ampicillin-resistant enterococci and VRE, at least 10 mg/kg of daptomycin or linezolid should be administered.[79] Combination therapy, consisting of a β-lactam plus an aminoglycoside (IV ampicillin or IV penicillin plus gentamicin) or β-lactam combination (IV ampicillin plus ceftriaxone) should be used in critically ill patients or those with suspected infective endocarditis.[77] IV ampicillin plus ceftriaxone is preferred if the isolate displays high-level aminoglycoside resistance or to avoid potential aminoglycoside toxicities. Because the aminoglycoside cannot penetrate the bacterial cell in the absence of the penicillin, enterococci is resistant to aminoglycosides by routine susceptibility testing (low-level resistance). However, in the presence of an agent that disrupts the cell wall such as penicillin, the aminoglycoside can gain entry, attach to bacterial ribosomes, and cause rapid cell death. A combination of vancomycin plus gentamicin is also synergistic against enterococci and is an appropriate therapy for the penicillin-allergic patient.[78,80,81] Other aminoglycosides, such as tobramycin and amikacin, cannot be substituted routinely due to resistance. Use of two β-lactam antimicrobials results in saturation of the cell membrane penicillin-binding proteins producing synergistic bactericidal activity.[77] Though the optimal duration of treatment remains undefined, the majority of cases can be treated with 5 to 7 days of therapy.[74]

Anaerobes

In most situations, treatment of anaerobic bacteremia is usually empiric based on historical susceptibility patterns due to difficulties associated with isolating an organism and performing susceptibility tests.[82] Limited data are available describing treatment of anaerobic bacteremia as management depends on resolution of the primary source.

Infective endocarditis

In most cases, vancomycin should be included in the empirical regimen to cover the most common causes of infective endocarditis, staphylococci, streptococci, and enterococci. Ceftriaxone should be added to cover aerobic gram-negative bacilli in patients with acute presentations. In patients with subacute presentations, ampicillin/sulbactam should be included in the empirical regimen to provide coverage against *S. aureus*, viridans group streptococci, enterococci, and HACEK organisms. Once causative bacteria is identified from blood or tissue cultures or serologic tests, antimicrobial therapy should be deescalated to target that specific pathogen.

β-Lactam antimicrobials, such as penicillin G (or ceftriaxone), nafcillin (or oxacillin), and ampicillin, remain the drugs of choice for streptococcal, staphylococcal, and enterococcal infective endocarditis, respectively. Tables 134-5 to 134-8 summarize these recommendations, which are discussed in more detail in the following sections. Tables 134-9 and 134-10 list drug dosing and monitoring recommendations for adult and pediatric patients, respectively. Because these guidelines focus on common causes of infective endocarditis, readers are referred to other references for more in-depth discussion of unusually encountered organisms.[5,6,83,84]

⑧ For some pathogens, such as enterococci, the use of synergistic antimicrobial combinations (including an aminoglycoside) is essential to obtain a bactericidal effect. Combination antimicrobials may also decrease the emergence of resistant organisms during treatment (eg, PVE caused by coagulase-negative staphylococci) and hasten the pace of clinical and microbiologic response (eg, some streptococcal and staphylococcal infections). Occasionally, combination treatment will result in a shorter treatment course.

Streptococcal Endocarditis

Streptococci are a common cause of infective endocarditis, with most isolates being viridans group streptococci. Viridans group streptococci refers to many different species, such as *Streptococcus sanguinis, Streptococcus oralis, Streptococcus salivarius, Streptococcus mutans*, and *Gemella morbillorum*.[5] These bacteria are common inhabitants of the human mouth and gingiva, and they are especially common causes of NVE.[5,42] During dental surgery, and even when brushing the teeth, these organisms can cause a transient bacteremia. In susceptible individuals, this may result in infective endocarditis. Streptococcal endocarditis is usually subacute, and the response to medical treatment is very good. *Streptococcus gallolyticus* (formerly known as *Streptococcus bovis*) is not a viridans group streptococcus, but it is included in this treatment group because it is penicillin-susceptible and requires the same treatment. *S. gallolyticus* is a non-enterococcal group D streptococci that resides in the GI tract. Infective endocarditis caused by this organism is often associated with a GI pathology, especially colon carcinoma. Endocarditis caused by *Streptococcus pneumoniae, Streptococcus pyogenes*, and group B, C, and G streptococci are uncommon, and their treatment is not well defined.[5,6]

Antibacterial regimens for viridans group streptococci are well studied, and in uncomplicated cases, the cure rate is expected to be more than 95%.[5,6] Viridans group streptococci are penicillin-susceptible, although some are more susceptible than others. Most are highly susceptible to penicillin G and have minimum inhibitory concentrations (MICs) of less than 0.12 μg/mL (mg/L).[45]

Approximately 10% to 20% are moderately susceptible (MIC 0.12-0.5 μg/mL [mg/L]). This different in vitro susceptibility led to recommendations that the MIC be determined for all viridans group streptococci to guide therapy. Some streptococci are deemed tolerant to the killing effects of penicillin, where the minimum bactericidal concentration (MBC) exceeds the MIC by 32 times. A tolerant organism is inhibited but not killed by an antimicrobial normally considered bactericidal.[5] Bactericidal activity is preferred for successful treatment of infective endocarditis; therefore, infections with a tolerant organism may relapse after treatment. Tolerant strains do not respond as readily to β-lactam therapy as non-tolerant ones, this phenomenon is primarily a laboratory finding with little clinical significance. Treatment for tolerant strains is identical to that for non-tolerant organisms, and measurement of the MBC is not recommended.

An assortment of regimens can be used to treat uncomplicated NVE caused by fully susceptible viridans group streptococci (see Table 134-5). Shorter-course antimicrobial regimens are advocated when possible. With susceptible streptococcal endocarditis (MIC ≤0.12 μg/mL [mg/L]), a 2-week regimen of high-dose parenteral penicillin G or ceftriaxone in combination with an aminoglycoside is as effective as 4 weeks of penicillin alone.[5]

Two single-drug regimens consist of high-dose parenteral penicillin G or ceftriaxone for 4 weeks. If short- term, 2-week therapy is desired, the guidelines suggest either high-dose parenteral penicillin G or ceftriaxone in combination with an aminoglycoside.[5] When used in select patients, this combination is as effective as 4 weeks of penicillin alone. Although streptomycin was listed in previous guidelines, gentamicin is the preferred aminoglycoside because serum drug concentrations are obtained easily, clinicians are more familiar with its use, and the few strains of streptococci resistant to the effects of streptomycin–penicillin remain susceptible to gentamicin–penicillin. Other aminoglycosides are not recommended. Whether extended-interval aminoglycoside dosing has a role in infective endocarditis continues to be debated. The combination of ceftriaxone (2 g daily) with gentamicin (3 mg/kg daily) for 2 weeks was compared with ceftriaxone (2 g daily) alone for 4 weeks for penicillin-susceptible streptococci and both regimens were safe and effective with similar clinical cure rates at 3 months following treatment.[85] Data support extended-interval dosing for the treatment of streptococcal infective endocarditis, and as compared with three-times- daily dosing this approach may have greater efficacy.[5]

The rationale for combination therapy against penicillin-susceptible viridans group streptococci is that enhanced activity against these organisms is usually observed in vitro when cell-wall-active agents are combined with aminoglycosides.[86] Combined treatment results in quicker sterilization of vegetations in animal models of endocarditis and probably explains the high response rates observed for patients treated for a total of 2 weeks.[5,85] The combined treatment, however, is not superior to penicillin alone.

The decision of which regimen to use depends on the perceived risk versus benefit. For example, a 2-week course of gentamicin in an elderly patient with renal impairment may be associated with ototoxicity, nephrotoxicity, or both. Furthermore, the 2-week regimen is not recommended for patients with known extracardiac infection. On the other hand, a 4-week course of penicillin alone generally entails greater expense, especially if the patient remains in the hospital. Monotherapy with once-daily ceftriaxone offers ease of administration, facilitates home healthcare treatment, and may be cost-effective.[5,6]

⑨ When a patient has a history of hypersensitivity with anaphylactic features to penicillin, vancomycin should be chosen for infective endocarditis caused by viridans group streptococci. When vancomycin is used, the addition of gentamicin is not recommended.[5] The published experience with penicillin is more extensive than with alternative regimens; consequently, a thorough allergy history and skin test, if available, must be obtained before a second-line therapy is administered.

For patients with complicated infections (eg, extracardiac foci) or when the streptococcus has an MIC of 0.12 to less than or equal to 0.5 μg/mL (mg/L), combination therapy with an aminoglycoside for the first 2 weeks and penicillin (higher dose) or ceftriaxone is recommended, followed by penicillin or ceftriaxone alone for an additional 2 weeks (see Table 134-5).[5] Some viridans group streptococci, previously referred to as nutritionally variant streptococci, have biologic characteristics that complicate diagnosis and treatment. For patients infected with nutritionally variant streptococci or when the *Streptococcus* spp. has an MIC of more than 0.5 μg/mL (mg/L), treatment should follow the enterococcal endocarditis treatment guidelines.

For patients with endocarditis of prosthetic valves or other prosthetic material caused by viridans group streptococci and *S. gallolyticus*, choices of treatment are similar to those without prosthetic material (eg, penicillin or ceftriaxone); however, treatment courses are extended to 6 weeks (see Table 134-6). For penicillin-susceptible isolates with an MIC of 0.12 μg/mL (mg/L) or less, high-dose parenteral penicillin G or ceftriaxone should be administered for 6 weeks with or without an aminoglycoside for the first 2 weeks. On the contrary, for isolates with an MIC greater than 0.12 μg/mL (mg/L), high-dose parenteral penicillin G or ceftriaxone combined with an aminoglycoside should be administered for the entire 6 weeks.

Staphylococcal Endocarditis

Endocarditis is most commonly caused by staphylococci, in particular *S. aureus*, mainly because of increased rates of injection drug use, more frequent use of vascular catheters, and increased frequency of valve replacement surgery.[19] Coagulase-negative staphylococci (usually *Staphylococcus epidermidis*) and *S. aureus* are prominent causes of PVE.

Staphylococcal endocarditis is not a homogeneous disease; appropriate management requires consideration of several questions: Is the organism methicillin resistant? Should combination therapy be used? Is the infection on a native or prosthetic valve? Does the patient have a history of injection drug use? Is the infection on the left or right side of the heart? Another consideration in staphylococcal endocarditis is that some organisms may exhibit tolerance to antimicrobials. Similar to streptococci, however, the concern for tolerance among staphylococci should not affect antimicrobial selection.[5]

The recommended therapy for patients with left-sided, native valve infective endocarditis caused by MSSA is 6 weeks of nafcillin or oxacillin; a longer duration of therapy may be needed for complicated infections (eg, presence of perivalvular abscess or septic metastases). From in vitro studies, the combination of an aminoglycoside and penicillinase-resistant penicillin or vancomycin enhances the activity of these drugs for MSSA. In animal models of endocarditis, combinations of penicillin with an aminoglycoside eradicate organisms from vegetations more rapidly than penicillins alone.[5,49] In most human studies, the addition of an aminoglycoside to nafcillin hastens the resolution of fever and bacteremia, but it does not affect survival or relapse rates and can increase nephrotoxicity.[49] As a result, the AHA and ESC guidelines no longer recommend the addition of gentamicin because clinical benefit has not been demonstrated and there is an increased risk of toxicity (see Table 134-5).

⑨ If a patient has a mild, delayed hypersensitivity to penicillin, cefazolin may be an effective alternative, but should be avoided for patients who report anaphylactic-type reactions to penicillins (see Table 134-5). The potential for a true immediate-type hypersensitivity should be assessed through a careful history or skin test, if available (Chapter e108). Vancomycin is an option for a patient with a positive skin test or a history of hypersensitivity with anaphylactic features to penicillin.

Vancomycin, however, kills *S. aureus* slowly and is inferior to antistaphylococcal or penicillinase-resistantpenicillins (eg, nafcillin, oxacillin) or cephalosporins (eg, cefazolin).[5] Alternatively, patients with hypersensitivity to penicillin can be considered for penicillin desensitization or daptomycin, a lipopeptide antimicrobial approved for right-sided infective endocarditis and *S. aureus* bacteremia.[5,6] Unfortunately, left-sided infective endocarditis caused by *S. aureus* continues to have a poor prognosis, with a mortality rate between 25% and 40%.[5] For reasons discussed in the following section, those with infective endocarditis associated with injection drug use have a more favorable response to therapy.

⑨ During the past decade, staphylococci more commonly have become resistant to antistaphylococcal or penicillinase- resistant penicillins (eg, MRSA). Although vancomycin is still the most commonly selected antimicrobial in these cases (see Table 134-5), susceptibility reports with an MIC greater than 2 μg/mL (mg/L) and reports of vancomycin-resistant *S. aureus* strains are increasing.[68] Success with daptomycin or linezolid has been demonstrated for these patients.[87–89] Use of daptomycin in clinical practice may extend beyond the FDA-approved indication of right-sided NVE, and higher doses of daptomycin (greater than or equal to 8 mg/kg/day) should be used. Additionally, higher doses may be preferred by some experts due to favorable drug tolerability and potential for decreased treatment-emergent resistance, although prospective, randomized clinical trials are lacking.[90–92] To date, linezolid has not been approved by the FDA for use in endocarditis as most available data are based on case reports, and there is concern regarding use of a bacteriostatic agent for this condition.[68,87] The presence or lack of a prosthetic heart valve in patients with a methicillin-resistant organism guides therapy and determines whether vancomycin should be used alone or, if a prosthetic valve is present, combination therapy is necessary (Table 134-6).[5]

Staphylococcus Endocarditis: PWID

Infective endocarditis in PWID is frequently (60%-70%) caused by *S. aureus*, although other organisms may be common in certain geographic locations.[6,19] In this setting, the tricuspid valve is frequently infected, resulting in right-sided infective endocarditis. Most patients have no history of valve abnormalities, are usually otherwise healthy, and have a good response to medical treatment. Nonetheless, surgery may be required.

As previously mentioned, an uncomplicated, left-sided MSSA endocarditis may be treated sufficiently with 6 weeks of monotherapy with an antistaphylococcal or penicillinase-resistant penicillin.[5] However, the clinical response with right- sided MSSA endocarditis in PWID is usually excellent and may be treated effectively (clinical and microbiologic cure exceeding 85%) with a 2-week course of nafcillin, oxacillin, or daptomycin.[5] Short 2-week courses of vancomycin for endocarditis in PWID are not recommended because of limited bactericidal activity, poor penetration into vegetations, and increased drug clearance in this population resulting in high rates of failure. If vancomycin is selected, the standard 6-week regimen should be used. Selection of a 2-week treatment duration may be appropriate for patients with MSSA right-sided endocarditis if they do not have signs of renal failure, extrapulmonary septic emboli, aortic or mitral valve involvement, or central nervous system infection, otherwise a 6-week regimen is indicated.[5]

Although previous guidelines emphasized combination therapy with an aminoglycoside for the 2-week duration based on earlier studies, the current recommendation for monotherapy is based on data showing that a 2-week regimen of an antistaphylococcal or penicillinase-resistant penicillin alone, without the addition of an aminoglycoside, is as effective as combined therapy in MSSA tricuspid valve endocarditis.[93] Daptomycin monotherapy with combination treatment (daptomycin plus 4 days of gentamicin) was no different in success rates but has higher rates of renal toxicity.[74] Vancomycin and daptomycin are both options for NVE caused by MRSA in PWID.

Alternative treatment approaches for staphylococcal endocarditis in PWID using oral antibacterial therapies (ciprofloxacin and rifampin) or long-acting lipoglycopeptides (eg, dalbavancin or oritavancin) have demonstrated efficacy.[94–96] However, concerns with resistance (eg, ciprofloxacin), patient adherence, and limited published data prohibit their routine use for the treatment of infective endocarditis in PWID.[5]

Staphylococcal Endocarditis: Prosthetic Valves

PVE accounts for 10% to 30% of all infective endocarditis cases.[6,15] Staphylococci (*S. aureus* and coagulase-negative staphylococci), gram-negative bacilli, and fungi are the main causes of early PVE, while the microbiology of late PVE mirrors that of NVE. An episode of PVE occurring within 2 months of surgery strongly suggests that the cause is staphylococci implanted during the procedure. Yet the risk of staphylococcal endocarditis remains elevated for up to 12 months after valve replacement.[97] Because this type of infective endocarditis is typically a nosocomial infection, methicillin-resistant organisms are common, and vancomycin is the cornerstone of therapy. Combination antimicrobials are recommended because of the high morbidity and mortality associated with PVE and its refractoriness to therapy.[5,68] Although the addition of rifampin to an antistaphylococcal or penicillinase-resistant penicillin or vancomycin does not result in predictable bacterial synergism, rifampin may have unique activity against staphylococcal infection that involves prosthetic material, where its addition results in a higher microbiologic cure rate.[5] Combination therapy also decreases the emergence of resistance to rifampin, which frequently occurs when it is used alone. For methicillin-resistant staphylococci (both MRSA and coagulase-negative staphylococci), vancomycin is recommended with rifampin for 6 weeks or more (Table 134-6). Due to the risk of developing on therapy resistance, rifampin should not be started until blood cultures have sterilized.[98] Gentamicin is added for the first 2 weeks if the organism is aminoglycoside susceptible; traditional dosing should be used as once-daily regimens have not been adequately evaluated in PVE and are not recommended.[5]

For MSSA, an antistaphylococcal or penicillinase-resistant penicillin is administered in place of vancomycin. PVE responds poorly to medical treatment and has a higher mortality compared with NVE. Valve dehiscence and incompetence can result in acute heart failure, and surgery is often a component of treatment.[5,60]

The use of anticoagulation is controversial in PVE. In general, those who require anticoagulation for a prosthetic valve should continue the anticoagulant cautiously during endocarditis therapy, unless a contraindication to therapy exists. It is recommended to hold all anticoagulation for at least 2 weeks for patients with *S. aureus* PVE if a recent CNS embolic event has occurred.[5]

Enterococcal Endocarditis

Enterococci are the third leading cause of infective endocarditis, but they are more resistant to therapy than staphylococci and streptococci.[78,80,99] Enterococci are noteworthy as no single antimicrobial is bactericidal. In addition, monotherapy with penicillin for infective endocarditis caused by enterococci results in relapse rates of 50% to 80%.[5,80,99] Thus, combination therapy consisting of a cell-wall–active agent such as a penicillin or vancomycin and an aminoglycoside (or cephalosporin with ampicillin) are necessary for bactericidal activity. Additionally, resistance to all available drugs is increasing.

Enterococcal endocarditis requires 4 to 6 weeks of IV ampicillin or IV penicillin G plus an aminoglycoside for cure (Table 134-7). IV ampicillin plus ceftriaxone is as effective and better tolerated as IV ampicillin plus gentamicin and should be considered as a treatment option.[5,6] A 6-week course is recommended for patients with symptoms lasting longer than 3 months and those with PVE. Streptomycin and gentamicin have similar efficacy, but gentamicin is preferred due to the inability to obtain streptomycin serum concentrations in most laboratories.[5,80] In the treatment of enterococcal endocarditis, relatively low serum concentrations of aminoglycosides appear adequate for successful therapy, such as a gentamicin peak concentration of approximately 3 to 4 μg/mL (mg/L; 6.3-8.4 μmol/L).[5,80,81] Treatment of enterococcal endocarditis does not have the high success rate seen with infective endocarditis caused by viridans group streptococci, presumably because the organism is more resistant to killing.

Although some data support the use of extended-interval aminoglycoside dosing for other types of endocarditis (eg, streptococci), the data are more vague regarding this strategy in enterococcal endocarditis.[80] Some studies suggest that extended-interval aminoglycoside dosing and short-interval (traditional) dosing are clinically equivalent, discordant studies imply otherwise.[77,81,100] Extended-interval dosing is appropriate in the setting of non-high-level aminoglycoside resistant (MIC <500 µg/mL [mg/L]) *E. faecalis* infective endocarditis and this strategy has been adopted by the new ESC Guidelines.[6,100] This recommendation differs from the current AHA guidelines, which continue to support traditional dosing.[5]

Resistance among enterococci to penicillins and aminoglycosides is increasing.[5] Enterococci that exhibit high-level resistance to streptomycin (MIC >2,000 µg/mL [mg/L]) are not synergistically killed by penicillin and streptomycin because the aminoglycoside either no longer binds to the ribosome or is inactivated by an aminoglycoside-modifying enzyme, streptomycin adenylase.[80] Because enterococci will appear resistant to aminoglycosides on routine susceptibility testing, the only way to distinguish high-level from low-level resistance is by performing special susceptibility tests using 500 to 2,000 µg/mL (mg/L) of the aminoglycoside.[78] High-level streptomycin-resistant enterococci occur with a frequency approaching 60%, and high-level resistance to gentamicin is now found in 10% to 50% of isolates. Although most gentamicin-resistant enterococci are resistant to all aminoglycosides (including amikacin), 30% to 50% remain susceptible to streptomycin.[80] The incidence of high-level aminoglycoside resistance is increasing; however, data on appropriate therapy are sparse, and therapeutic options are few.[77,80,81]

In addition to isolates with high-level aminoglycoside resistance, β-lactamase-producing enterococci (especially *E. faecium*) have been reported. If these organisms are discovered, use of vancomycin or ampicillin-sulbactam in combination with gentamicin should be considered. Treating multidrug-resistant enterococci, such as VRE, is difficult, and data on appropriate therapy are sparse. Guidelines suggest either linezolid or daptomycin (at least 10 mg/kg), although use of either agent has produced conflicting results.[5,6] Surgery and replacement of the infected cardiac valve may be the only cure.

HACEK Group

Fastidious gram-negative bacteria from the group of bacteria including *Haemophilus parainfluenzae*, *Haemophilus aphrophilus*, *Aggregatibacter* species, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae* (HACEK group) account for 0.8% to 6% of infective endocarditis cases.[101] Frequently, these types of infective endocarditis present as subacute illnesses with large vegetations and emboli. These oropharyngeal organisms are slow growing and should be considered as possible causes of "culture-negative" endocarditis. With proper treatment, infectious endocarditis caused by HACEK organisms has a low mortality rate. β-Lactamase–producing organisms are occurring more often; hence, HACEK organisms should be considered resistant to ampicillin alone and should not be used unless in vitro susceptibility testing is adequate. Ceftriaxone, or an alternate third- or fourth-generation cephalosporin, is the preferred treatment in most cases. Ciprofloxacin may be considered as an option if a hypersensitivity to cephalosporins is present (Table 134-8).[5,6] Treatment is usually for 4 weeks, but it should be extended to 6 weeks in PVE caused by one of these organisms.

Less Common Types of Infective Endocarditis

Atypical Microorganisms

Endocarditis caused by organisms, such as *Bartonella* spp., *C. burnetii*, *Brucella* spp., *Candida* spp., and *Aspergillus* spp., *Legionella* spp., and gram-negative bacilli (eg, *Pseudomonas*), is relatively uncommon. Medical therapy for infective endocarditis caused by these organisms is usually unsuccessful.[5,6] Consultation with an infectious diseases expert is warranted when these microorganisms are identified.

In addition to *Pseudomonas* spp., other gram-negative bacilli that have been implicated include *Salmonella* spp., *E. coli, Citrobacter* spp., *Klebsiella* spp., *Enterobacter* spp., *Serratia marcescens, Proteus* spp., and *Providencia* spp. These infections have a poor prognosis, with mortality rates as high as 60% to 80%. Cardiac surgery in concert with an extended duration of combination antibacterial therapy is recommended (class IIa; level of evidence: B) for most patients with gram-negative bacillary infective endocarditis. Readers are referred to the AHA guidelines for more extensive review of treatment regimens for infective endocarditis due to *Pseudomonas* spp. and unusual gram-negative bacteria.[5]

Fungi cause less than 2% of endocarditis cases; most patients with fungal endocarditis have undergone recent cardiovascular surgery, are PWID, have received prolonged treatment with indwelling central venous catheters, or are immunocompromised.[102] *Candida* spp. and *Aspergillus* spp. are the most commonly involved, and the mortality rate is high (>80%) for the following reasons: (1) large, bulky vegetations that often form, (2) systemic septic embolization that may occur, (3) the tendency of fungi to invade the myocardium, (4) poor penetration of vegetations by antifungals, (5) the low toxic-to-therapeutic ratio of agents such as amphotericin B, and (6) the lack of consistent fungicidal activity of available antifungal agents.[5,6,102] When fungal infective endocarditis is identified, a combined medical–surgical approach is warranted. Because these infections occur infrequently, scant clinical data are available to make solid treatment recommendations. Amphotericin B with or without flucytosine or high dose echinocandin is the recommended pharmacologic approach for *Candida* spp. endocarditis while voriconazole is suggested for those with *Aspergillus* spp. endocarditis.[5,6,84,103] Greater than 6 weeks of therapy is usually recommended, followed by life-long suppressive therapy with an oral azole in most cases.

C. burnetii (Q fever), an obligate intracellular bacterium, is most likely to be identified via serology or PCR testing since it cannot be isolated from routine blood cultures. It is a common cause of infective endocarditis in certain areas of the world where goat, cattle, and sheep farming are widespread. The most favorable therapy for Q fever is unknown but may include doxycycline with hydroxychloroquine, trimethoprim/sulfamethoxazole, rifampin, or fluoroquinolones for at least 18 months.[104] *Brucella* spp. are facultative intracellular gram-negative bacilli. Humans are infected by this organism after ingesting infected unpasteurized dairy products or undercooked meat, inhaling infectious aerosols, or contacting infected tissues. This type of infective endocarditis is more common in veterinarians and livestock handlers. Cure requires valve replacement and antimicrobial agents including doxycycline with streptomycin, gentamicin, or doxycycline with trimethoprim–sulfamethoxazole or rifampin for an extended period (6 weeks to months).[105]

Culture-Negative Endocarditis

Sterile blood cultures are reported in up to 40% of patients with infective endocarditis if strict diagnostic criteria are used.[2,6,41] This type of infective endocarditis may occur as a result of previous antimicrobial therapy (most common), unidentified subacute right-sided infective endocarditis, slow-growing fastidious organisms, non-bacterial etiologies (eg, fungi), non-infective endocarditis, and improperly collected blood cultures. When blood cultures from patients suspected of infective endocarditis show no growth after 48 to 72 hours, cultures should be held for up to a month and special testing techniques (eg, serological analysis, PCR) pursued to detect fastidious or non-bacterial organisms.[5,43]

The AHA guidelines provide general recommendations for culture-negative infective endocarditis (Table 134-8) and suggest that therapy should be guided based on the individual patient’s medical history and epidemiological risks identified. Selection of treatment can be difficult, balancing the need to cover all likely organisms against potential toxic drug effects (eg, aminoglycosides). Antimicrobial selection should involve consultation with an infectious diseases specialist. Irrespective of the chosen treatment, extended antimicrobial therapy is required. The empirical approaches for culture-negative infective endocarditis highlight the need for proper collection and monitoring of blood cultures and an extensive medication history.

EVALUATION OF THERAPEUTIC OUTCOMES

The evaluation of patients treated for bacteremia or infective endocarditis includes assessment of disease signs and symptoms, blood cultures, microbiologic tests, inflammatory markers, serum drug concentrations, and other tests to evaluate organ function. Table 134-10

TABLE 134-10

Drug Monitoring of Select Agents

Drug	Major Adverse Drug Reactions	Monitoring Parameters	Comments
Daptomycin	Myopathy, rhabdomyolysis	CPK at least weekly; monitor for signs and symptoms of muscle pain	More frequent monitoring may be warranted in patients with renal dysfunction or receiving concomitant therapy with HMG-CoA reductase inhibitors; discontinue if symptomatic and CPK >5 times the ULN or if CPK ≥10 times ULN
Gentamicin	Nephrotoxicity, ototoxicity, neuromuscular blockade	When dosed three times daily: ○ Target peak serum concentrations of 3-4 µg/mL (mg/L; 6.3-8.4 µmol/L) and trough serum concentrations of <1 µg/mL (mg/L; <2.1 µmol/L)	Avoid concomitant use of other nephrotoxic agents such as diuretics, non-steroidal antiinflammatory drugs, and radiocontrast media. Avoid rapid IV administration
Linezolid	Thrombocytopenia, optic, or peripheral neuropathy	Platelet counts at baseline and weekly, visual changes	More common with prolonged therapy (≥2 weeks for thrombocytopenia, >28 days for visual symptoms); avoid concomitant myelosuppressive agents
Rifampin	Hepatotoxicity	Baseline liver function tests, and then at least every 2-4 weeks during therapy	Avoid concomitant medications that cause hepatotoxicity; may cause red or orange discoloration of bodily secretions (urine, sweat, tears)
Vancomycin	Nephrotoxicity, vancomycin infusion reaction	AUC-guided or trough-guided serum concentration monitoring	Vancomycin infusion reaction may be managed by prolonging the infusion time from 1 to 2 hr; administration of an antihistamine prior to loading or maintenance doses may also be considered

CPK, creatinine phosphokinase; ULN, upper limit of normal; AUC, area under the curve.

Signs and Symptoms

Time to clinical improvement in patients with bacteremia largely depends on the infectious etiology, primary source of infection, presence of secondary metastatic foci, and degree of source control. In general, patients with gram-negative bacteremia clinically improve at a faster rate than those with gram-positive bacteremia, especially *S. aureus*.[30]

Fever usually subsides within 1 week of initiating therapy for patients with infective endocarditis.[23] Persistence of fever may indicate ineffective antimicrobial therapy, emboli, right-sided endocarditis, intravascular catheter infections, or drug reactions. For some patients, fever may persist even with appropriate antimicrobial therapy. With defervescence, the patient should begin to feel better, and other symptoms, such as lethargy or weakness, should subside. Echocardiography, typically a TTE, should be performed when antimicrobial therapy has been completed to determine new baseline cardiac function (eg, ventricular size and function).[5]

Blood Cultures

After initiating antimicrobial therapy, follow-up blood cultures should be obtained every 24 to 48 hours until sterile in most patients as duration of bacteremia may impact duration of therapy.[30] With *S. aureus* bacteremia, positive follow-up blood cultures are associated with increased mortality.[106]

Additionally, positive follow-up blood cultures, indicative of prolonged duration of bacteremia, may suggest that the antimicrobials are inactive against the pathogen, the doses are not producing adequate concentrations at the site of infection, or lack of source control in some patients.[107] In most situations, the duration of therapy should be determined beginning on the first day blood cultures were negative in patients with previously positive blood cultures. Alternatively, the duration of therapy should be counted from the first postoperative day in patients who undergo valve surgery with intraoperative findings of a paravalvular abscess or resultant positive culture from the valve tissue. During the remainder of therapy, frequent blood cultures are not necessary but should be obtained if fever recurs.[4]

However, positive follow-up blood cultures in gram-negative bacteremia are uncommon.[30,108] As a result, follow-up blood cultures may be unnecessary except in patients who remain febrile despite antimicrobial therapy, relapse, or lack source control. In these cases, duration of therapy should begin on the first day of active therapy based on antimicrobial susceptibility testing.

Microbiologic Tests

⑩ Identification and susceptibility testing should be performed on all organisms isolated from blood cultures to guide definitive therapy in patients with bacteremia or infective endocarditis.[5,49,65] The agent being used should be tested, as well as alternatives that may be required if intolerance, allergy, or resistance occurs. Occasionally, it is useful to determine whether synergy exists for antimicrobial combinations, although synergistic regimens usually can be predicted from the literature.

Inflammatory Markers

Inflammatory markers are commonly used in infectious diseases processes for diagnosing, monitoring of clinical outcomes, and assisting clinicians with evaluating the efficacy of antibacterial therapy. Only one inflammatory marker, rheumatoid factor (RF), is part of the Modified Duke Criteria for diagnosis. Other inflammatory markers, such as ESR, CRP, and procalcitonin (PCT), have all been investigated for evaluating the outcomes of patients with bacteremia and infective endocarditis.[109,110] While these markers may be beneficial in assessing clinical outcomes, further evidence is needed to establish routine use for infective endocarditis.

Serum Drug Concentrations

Of the agents used for bacteremia and infective endocarditis, therapeutic drug monitoring is routinely available for aminoglycosides (except streptomycin) and vancomycin. Few data, however, support attaining any specific serum concentrations for patients with infective endocarditis. In general, serum concentrations of the antibacterial should exceed the MIC of the organisms.

When aminoglycosides are administered for infective endocarditis caused by gram-positive cocci with a traditional three-times-daily regimen, peak serum concentrations are recommended to be on the low side of the traditional ranges (3-4 μg/mL [mg/L; 6.3-8.4 μmol/L] for gentamicin). If extended-interval dosing is used, which is only recommended in streptococcal infective endocarditis, the most appropriate method of monitoring has not been determined. When vancomycin is administered, the primary goal is to ensure adequate concentrations, based on area under the curve (AUC)-guided or trough-guided serum concentration monitoring.

PREVENTION

Antimicrobial prophylaxis is used as an attempt to prevent infective endocarditis for patients who are at the highest risk.[5–7] The use of antimicrobials for this purpose requires consideration of (1) cardiac conditions associated with endocarditis, (2) procedures causing bacteremia, (3) organisms likely to cause endocarditis, and (4) pharmacokinetics, spectrum, cost, adverse effects, and ease of administration of available antimicrobial agents. The objective of prophylaxis is to diminish the likelihood of infective endocarditis in high-risk individuals from procedures that result in bacteremia. Although there are no prospective, controlled human trials demonstrating that prophylaxis in high-risk individuals protects against the development of endocarditis during bacteremia-inducing procedures, animal studies suggest possible benefit.[7] Furthermore, many causes of infective endocarditis appear not to be secondary to an invasive procedure. Bacteremia as a consequence of daily activities may be the major culprit, and the value of antimicrobial prophylaxis before bacteremia-causing procedures has been questioned. The effectiveness or ineffectiveness of antimicrobial prophylaxis has not been proven, and the common practice of using antimicrobial therapy in this setting remains controversial. The mechanism of a beneficial effect in humans is unclear, but antimicrobials may decrease the number of bacteria at the surgical site, kill bacteria after they are introduced into the blood, and prevent adhesion of bacteria to the valve.

Regardless of the controversy about whether prophylactic antimicrobials should be used, infective endocarditis prophylaxis is recommended in select situations in those with underlying high-risk cardiac conditions. The AHA released updated guidelines that better define who should and should not receive infective endocarditis prophylaxis.[7]

Key points are that (1) only a small number of cases of infective endocarditis might be prevented with antimicrobial prophylaxis for dental procedures, even if 100% effective; (2) infective endocarditis prophylaxis should be recommended only for patients with underlying cardiac conditions associated with the highest risk, which includes presence of a prosthetic heart valve, prosthetic material used for cardiac valve repair, prior diagnosis of infective endocarditis, cardiac transplantation with subsequent valvulopathy, CHD, for dental procedures involving manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa, invasive respiratory procedures involving an incision or biopsy, or invasive procedures involving infected skin, skin structures, or musculoskeletal tissue; (3) prophylaxis is not recommended based solely on an increased lifetime risk of acquisition of infective endocarditis; and (4) administration of antimicrobials solely to prevent endocarditis is not recommended for patients who undergo a gastrointestinal tract or genitourinary procedure.

To determine whether a patient should receive prophylactic antimicrobials, one needs to assess the patient’s risk and whether he or she is undergoing a procedure resulting in bacteremia. When antimicrobial prophylaxis is appropriate, a single 2-g dose of amoxicillin is recommended for adult patients at risk, given 30 to 60 minutes before undergoing procedures associated with bacteremia. Because the duration of antimicrobial prophylaxis appears to be relatively short, guidelines do not advocate a second oral dose of amoxicillin, which was recommended previously. Alternative prophylaxis regimens for patients with hypersensitivity to penicillins or those unable to take oral medications are also provided. Clindamycin is no longer recommended for prophylaxis for dental procedures due to greater risk of adverse reactions compared to other prophylactic antimicrobials. A summary of guideline recommendations is available in Table 134-11. Refer the full AHA guideline for more detailed information.[7]

TABLE 134-11

Prophylaxis of Infective Endocarditis

Highest Risk Cardiac Conditions	Presence of a prosthetic heart valve Prosthetic material used for cardiac valve repair Prior diagnosis of infective endocarditis Cardiac transplantation with subsequent valvulopathy Congenital heart disease (CHD)[1]	
Types of procedures	Dental procedures that require perforation of the oral mucosa or manipulation of the periapical region of the teeth of gingival tissue Invasive respiratory procedures involving an incision or biopsy Invasive procedures involving infected skin, skin structures, or musculoskeletal tissue	
Antimicrobial Options	**Adult Doses[2]**	**Pediatric Doses[2] (mg/kg)**
Oral amoxicillin	2 g	50
IM or IV ampicillin[3]	2 g	50
IM or IV cefazolin or ceftriaxone[3–5]	1 g	50
Oral cephalexin[4–6]	2 g	50
Oral doxycycline[5]	100 mg	<45 kg, 4.4 mg/kg or >45 kg, 100 mg
Oral azithromycin or clarithromycin[5]	500 mg	15
IV vancomycin[b,3,5]	15 to 20 mg/kg (not to exceed 2 g per dose)	15 (maximum dose of 1 g)

[1] Includes only the following: unrepaired cyanotic CHD, prophylaxis within the first 6 months of implanting prosthetic material to repair a congenital heart defect, and repaired CHD with residual defects at or adjacent to prosthetic material.

[2] All one-time doses administered 30-60 minutes prior to initiation of the procedure except for IV vancomycin which should be administered 120 minutes prior to the procedure.

[3] For patients unable to tolerate oral medication.

[4] Should be avoided in patients with immediate-type hypersensitivity reaction to penicillin or ampicillin (eg, anaphylaxis, urticaria, or angioedema).

[5] Option for patients with non-immediate hypersensitivity reaction to penicillin or ampicillin.

[6] May substitute with an alternative first- or second-generation cephalosporin at an equivalent dose.

Data from References 7,111.

OPAT	outpatient antimicrobial therapy
PCR	polymerase chain reaction
PCT	procalcitonin
PVE	prosthetic valve endocarditis
PWID	persons who inject drugs
RF	rheumatoid factor
SBT	serum bactericidal titer
TEE	transesophageal echocardiography

TTE	transthoracic echocardiography
ULN	upper limit of normal
VRE	vancomycinresistant enterococcus

SELF-ASSESSMENT QUESTIONS

1. Which of the following are the two most important parameters for the diagnosis of infective endocarditis?

A. Laboratory abnormalities and positive blood cultures

B. Positive blood cultures and echocardiographic changes

C. Electrocardiogram changes and positive physical findings

D. Positive physical findings and positive blood cultures

2. Which of the following most likely represents a patient with true bacteremia?

A. 62-year-old man admitted for diabetic ketoacidosis with *Staphylococcus epidermidis* isolated from 1 of 4 blood culture bottles

B. 22-year-old woman with a history of intravenous drug use with *Staphylococcus aureus* isolated from 2 of 4 blood culture bottles

C. 58-year-old woman admitted with a newly diagnosed DVT and *Bacillus* spp. isolated from both sets of blood cultures

D. 99-year-old man admitted for failure to thrive with *Staphylococcus haemolyticus* isolated from 2 of 4 blood culture bottles

3. Which statement is *true* concerning echocardiography in the diagnosis of infective endocarditis?

A. A negative transthoracic echocardiogram (TTE) excludes a diagnosis of infective endocarditis

B. Transesophageal echocardiogram (TEE) has better sensitivity than transthoracic echocardiogram (TTE) for detecting vegetations

C. Transesophageal echocardiogram (TEE) is unnecessary in patients with congenital heart disease, previous endocarditis, new murmur, or heart failure

D. Transesophageal echocardiogram (TEE) has good sensitivity but poor specificity for detecting vegetations

4. 76-year-old man with a history of dental abscess was admitted to the clinic with persistent fever and malaise for the last month. A transthoracic echocardiogram (TTE) revealed a large mitral valve vegetation. Which of the following is the most likely etiology?

A. Group A streptococci

B. Viridans group streptococci

C. *Staphylococcus epidermidis*

D. *Enterococcus faecalis*

5. 35-year-old man with a history of injection drug use was admitted with fevers and rigors and blood cultures revealed gram-positive cocci in pairs and clusters. He has no known drug allergies, has normal renal function, and appears in no apparent distress. Which of the following is the most appropriate empiric antibacterial therapy?

A. Vancomycin

B. Cefazolin

C. Nafcillin

D. Piperacillin/tazobactam

6. Which of the following is associated with the *highest* risk of developing infective endocarditis?

A. Mitral valve prolapse with regurgitation

B. Presence of a prosthetic heart valve

C. Rheumatic fever without valvular defects

D. Intravenous drug abuse

7. Which of the following represents the most likely primary source for *Escherichia coli* bacteremia?

A. Urogenital procedure

B. Skin and soft tissue infection

C. Community acquired pneumonia

D. Total knee arthroplasty

8. Which situation is *most* likely to lead to “culture-negative” infective endocarditis?

A. Use of antimicrobials prior to blood culture sampling

B. Gram-negative bacteria from the HACEK group (eg, *Kingella kingae*)

C. Non-bacterial etiologies (eg, fungi)

D. Unidentified subacute, left-sided infective endocarditis

9. A patient presents with complaints of fevers, chills, malaise, and dyspnea for the past 2 days. A grade 3/6 systolic murmur and thin, linear hemorrhages under the fingernail beds are discovered on examination. Based on these findings, the patient is suspected to have infective endocarditis. Which of the following would be the most appropriate empirical antimicrobial regimen?

A. Cefazolin 2 g IV every 8 hours

B. Vancomycin 15 mg/kg IV every 12 hours

C. Vancomycin 15 mg/kg IV every 12 hours plus ampicillin/sulbactam 3 g IV every 6 hours

D. Vancomycin 15 mg/kg IV every 12 hours plus ceftriaxone 2 g IV every 12 hours

10. Which of the following would be the most appropriate antimicrobial regimen for methicillin-resistant *Staphylococcus aureus* (MRSA) prosthetic valve infective endocarditis?

A. Vancomycin 15 mg/kg IV every 12 hours for 6 weeks

B. Vancomycin 15 mg/kg IV every 12 hours plus gentamicin 1 mg/kg IV every 8 hours for 6 weeks

C. Vancomycin 15 mg/kg IV every 12 hours and rifampin 300 mg po every 8 hours for 6 weeks plus gentamicin 1 mg/kg IV every 8 hr for the first 2 weeks

D. Doxycycline 100 mg IV every 12 hours and rifampin 300 mg po every 8 hours for 6 weeks plus gentamicin 1 mg/kg IV every 8 hours for the first 2 weeks

11. In which of the following patients could intravenous antimicrobial therapy be transitioned to oral antimicrobial therapy to yield similar safety and efficacy outcomes?

A. 65-year-old man with methicillin-resistant *Staphylococcus aureus* (MRSA) bacteremia after recent total hip arthroplasty

B. 23-year-old woman with a pan susceptible *Klebsiella pneumoniae* bacteremia due to pyelonephritis

C. 47-year-old woman with fluoroquinolone-resistant *Pseudomonas aeruginosa* lifeport associated bacteremia

D. 62 year old man with methicillin-susceptible *Staphylococcus aureus* (MSSA) bacteremia due right lower extremity osteomyelitis

12. In which of the following patients would short course (7 days) of treatment for gram-negative bacteremia be most appropriate?

A. 24-year-old woman with a history of intravenous drug use with *Enterobacter cloacae* bacteremia and a paravalvular abscess

B. 66-year-old woman with *Escherichia coli* bacteremia due a urinary tract infection

C. 30-year-old man with *Serratia marcescens* bacteremia due to recent lumbar fusion

D. 40-year-old man with *Pseudomonas aeruginosa* bacteremia complicated by a prosthetic valve endocarditis

13. What is the *most* common organism causing infective endocarditis?

A. *Candida albicans*

B. *Enterococcus faecalis*

C. *Staphylococcus aureus*

D. *Viridans group streptococcus*

14. Which of the following represents a patient with uncomplicated *Staphylococcus aureus* bacteremia?

A. 26-year-old woman with no significant past medical history who developed a central line-associated MSSA bacteremia while being treated in the ICU for pancreatitis

B. 44-year-old man with a history of IV drug use with MRSA bacteremia and tricuspid infective endocarditis

C. 44-year-old man with persistent MSSA bacteremia secondary to prosthetic joint infection

D. 68-year-old woman with MRSA bacteremia and an infected cardiac implantable electronic device

15. Which of the following represents the most appropriate events in the management of *Staphylococcus aureus* bacteremia?:

A. infectious diseases consultation, source control, appropriate antimicrobial therapy

B. echocardiography, repeat blood cultures, appropriate antimicrobial therapy

C. infectious diseases consultation, echocardiography, source control, repeat blood cultures, appropriate antimicrobial therapy

D. infectious diseases consultation, echocardiography, repeat blood cultures, appropriate antimicrobial therapy

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** Based on the Modified Duke Criteria, diagnosis of definite infective endocarditis requires positive blood cultures and evidence of endocardial involvement (Diagnosis section, Infective Endocarditis subsection, Table 134-6).

2. **A.** *Staphylococcus aureus* should always be considered pathogenic whereas *Staphylococcus epidermidis*, *Staphylococcus haemolyticus*, and *Bacillus* spp., are unlikely pathogens when recovered from blood cultures (Diagnosis section, Bacteremia subsection, Table 134-5).

3. **B.** Echocardiography is critical in diagnosis of infective endocarditis. While transthoracic echocardiograms (TTE) are performed first due to accessibility, transthoracic echocardiograms (TEE) are more sensitive and specific (90%-100% and 40%-66%, respectively). TEE should be performed in patients with CHD, previous endocarditis, new murmur, heart failure, or other stigmata of infective endocarditis (Diagnosis section, Infective Endocarditis subsection).

4. **B.** Viridans group streptococci are common inhabitants of the human mouth and gingiva, and they are especially common causes of endocarditis involving native valves which presents in a subacute fashion (Pharmacologic Therapy section, Infective Endocarditis subsection, Streptococcal Endocarditis).

5. **C.** Empirical therapy in patients with suspected *S. aureus* bacteremia based on gram-positive cocci in pairs and clusters from blood cultures, prior to susceptibility results, should include active against MRSA with either vancomycin or daptomycin in the majority of cases due to the increased rate of MRSA identified in hospital- and community-acquired bacteremias (Pharmacologic Therapy section, Bacteremia subsection, *Staphylococcus aureus*).

6. **A.** Presence of a prosthetic heart valve is associated with the greatest risk of infective endocarditis (Epidemiology section, Table 134-2).

7. **B.** Enterobacterales, which includes *E. coli*, bacteremia is most likely caused by genitourinary or gastrointestinal or respiratory tract sources, as well as translocation from genitourinary or gastrointestinal due to disruption or procedure (Non-pharmacologic Therapy section, Bacteremia subsection, Source control, Table 134-7).

8. **A.** "Culture-negative" infective endocarditis describes a patient in whom a clinical diagnosis of infective endocarditis is likely, but blood cultures do not yield a pathogen, which is most often due to previous antimicrobial therapy (Diagnosis section, Infective Endocarditis subsection).

9. **D.** In patients with acute presentations of infective endocarditis, IV vancomycin should be combined with cefepime to cover the most common causes of infective endocarditis, staphylococci, streptococci, enterococci, and aerobic gram-negative bacilli (Pharmacologic Therapy section, Infective Endocarditis subsection, Streptococcal Endocarditis).

10. **D.** 6 Weeks of IV vancomycin and PO rifampin should be combined with 2 weeks of IV gentamicin in patients with methicillin-resistant *Staphylococcus aureus* (MRSA) prosthetic valve endocarditis (Pharmacologic Therapy section, Infective Endocarditis subsection, Staphylococcal Endocarditis, Table 134-9).

11. **B.** Oral antimicrobial therapy is not recommended for patients with St*aphylococcus aureus* bacteremia. Although oral antimicrobial therapy can be used for gram-negative bacteremia, fluoroquinolones are the only oral option for *Pseudomonas aeruginosa* (Pharmacologic Therapy section, Bacteremia subsection)

12. **B.** Patients with uncomplicated gram-negative bacteremia can be treated with 7 days of antimicrobial therapy (Pharmacologic Therapy section, Bacteremia subsection, Gram-Negative Bacilli).

13. **C.** Endocarditis is most commonly caused by staphylococci, in particular *S. aureus* (Epidemiology section, Table 134-2).

14. **A.** To meet criteria for uncomplicated or low-risk *S. aureus* bacteremia, all of the following criteria must be met: (1) sterile repeat blood cultures 48 to 96 hr after the initial positive culture, (2) defervescence within 72 hr after initiation of active therapy, (3) exclusion of infective endocarditis/secondary metastatic infection, (4) no implanted prostheses (eg, prosthetic valves, cardiac devices, or arthroplasties), (5) not dependent on hemodialysis (Pharmacologic Therapy section, Bacteremia subsection, *Staphylococcus aureus*).

15. **C.** Treatment of *S. aureus* bacteremia includes source control, consultation with infectious diseases, echocardiography to evaluate for infective endocarditis, repeat blood cultures, and appropriate antimicrobial therapy. (Non-pharmacologic Therapy section, Bacteremia subsection, and Pharmacologic Therapy section, Bacteremia subsection, *Staphylococcus aureus*)

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 135: Tuberculosis

Rocsanna Namdar; Charles Peloquin

KEY CONCEPTS

KEY CONCEPTS

①Tuberculosis (TB) is one of the most prevalent communicable infectious diseases on earth; and it remains out of control in many developing nations. These nations require medical and financial assistance from developed nations in order to control the spread of TB globally.

②In the United States, TB disproportionately affects the foreign born and other ethnic minorities, reflecting immigration patterns and greater ongoing transmission in these communities. Additional TB surveillance and preventive treatments are required within these communities.

③TB is the leading cause of death in human immunodeficiency virus (HIV) infection worldwide. Coinfection with HIV and TB accelerates the progression of both diseases, thus, requiring rapid diagnosis and treatment of both diseases.

④Mycobacteria are slow-growing organisms; in the laboratory, they require special stains, special growth media, and long periods of incubation to isolate and identify.

⑤TB can produce atypical signs and symptoms in infants, older adults, and immunocompromised hosts, and it can progress rapidly in these patients.

⑥Latent TB infection (LTBI) can lead to reactivation disease years after the primary infection occurred.

⑦The patient suspected of having active TB disease must be isolated until the diagnosis is confirmed and the patient is no longer contagious. Often, isolation takes place in specialized “negative-pressure” hospital rooms to prevent the spread of TB.

⑧Isoniazid and rifampin are the two most important drugs in the treatment of TB. Organisms resistant to both these drugs (multidrug-resistant TB [MDR-TB]) are much more difficult to treat.

⑨Directly observed treatment (DOT) should be used whenever possible to reduce treatment failures and the selection of drug-resistant isolates.

⑩To avoid the development of resistance, never add a single drug to a failing TB treatment regimen.

BEYOND THE BOOK

BEYOND THE BOOK

Read and review the study questions in the Self-Study Module 6 on Tuberculosis: Managing Tuberculosis Patients and Improving Adherence located on the Centers for Disease Control and Prevention (CDC) website: Self-Study Modules - Continuing Education Activities TB CDC Module6.pdf (cdc.gov). Focus on the Adherence to Treatment section (pages 27-55). This module is designed to teach healthcare providers about methods to improve medication adherence in different types patients with tuberculosis disease. Strategies to improve patient adherence are described including directly observed therapy, incentives, and education. The module is a useful tool for students to enhance their understanding of assessment and implementation steps in the patient care process.

INTRODUCTION

① Tuberculosis (TB) remains a leading infectious killer globally. TB is caused by *Mycobacterium tuberculosis*, which can produce either a silent, latent infection, or a progressive, active disease.[1] Left untreated or improperly treated, TB causes progressive tissue destruction and, eventually, death. Because of renewed public health efforts, TB rates in the United States continue to decline. In contrast, TB remains out of control in many developing countries.[1] Given increasing drug resistance, it is critical that a major effort be made to control TB before the most potent drugs are no longer effective.

TB rates generally have risen with increasing urbanization and overcrowding because it is easier for an airborne disease to spread when people are living in closer proximity to each other. Hence, TB became a significant pathogen in Europe during the Middle Ages and peaked during the Industrial Revolution, when it caused significant mortality in Europe and in the United States.[1] This dire threat led to the rise of public health departments and to procedures such as the isolation of infected patients. Thus, TB was directly responsible for many of the healthcare practices that are used today. Unfortunately, in developing nations, some of these practices are not widely available, and TB continues to rage unabated (Fig. 135-1).

FIGURE 135-1

Reported tuberculosis cases in the United States. (Note: Number of tuberculosis cases among persons with unknown origin are not shown (range = 2-61). Total rate includes cases among persons with unknown national origin. Rates for non–US-born and US-born persons were calculated by using midyear Current Population Survey estimates. Total rate was calculated by using midyear population estimates from the US Census Bureau.) *(Reprinted from reported Tuberculosis in the United States, 2017. Atlanta, GA: US Department of Health and Human Services, CDC; 2018.)*

A bar graph shows the number of tuberculosis cases reported in the United States from 1962 to 2017.

EPIDEMIOLOGY

Over one-fourth of the world's population is infected by *M. tuberculosis*.[1] In 2019, there were about 10 million new cases and 1.2 million deaths from TB reported.[1] In the United States, 9 million people are latently infected with *M. tuberculosis*, meaning that they are not currently sick but that they could fall ill with TB at any time.[2] In 2019, 8,916 new TB cases were reported in the United States.[2] A further drop occurred in 2020, driven largely by measures to prevent another respiratory pathogen, COVID-19.[3] TB cases in the United States declined by approximately 5% per year from 1953 to 1983.[2] Starting in 1984, cases plateaued, and then rose from 1988 to 1992.[2] Since 1993, more effective infection control practices and treatment protocols have reduced TB rates significantly. However, the eradication of TB from the United States remains difficult because it is tied to immigration from high incidence countries.[1–3]

Risk Factors for Infection

Location and Place of Birth

California, Florida, New York, and Texas accounted for just over half of the TB cases reported nationally in 2019.[3] Within these states, TB is most prevalent in large urban areas and among those born outside the United States in high TB incidence countries.[3]

The percentage of foreign-born persons with TB in the United States has increased annually, reaching 71% in 2019.[3] In 2019, over half of foreign-born persons with TB originated from five countries: Mexico, the Philippines, India, Vietnam, and China.[3] Healthcare workers must consider TB when caring for patients from these countries who experience symptoms such as cough, fever, and weight loss. Furthermore, foreign-born persons account for almost 90% of the multidrug-resistant (MDR) TB cases in the United States.[3]

Close contacts of pulmonary TB patients such as family members, coworkers, or coresidents in places such as prisons, shelters, or nursing homes are most likely to become infected. The more prolonged the contact, the greater is the risk, with infection rates as high as 30%.[2,3] People with TB frequently have limited access to healthcare, live in crowded conditions, or are homeless.[2,3] Many have histories of alcohol use disorder or illicit drug use, and are coinfected with hepatitis B or HIV. These concurrent social and health problems make treating some TB patients particularly challenging.

Ethnicity and Age

② In the United States, TB disproportionately affects the foreign-born and other ethnic minorities. In 2019, Asians accounted for 36% percentage of total TB cases; Hispanic/Latino people for 30%, and Blacks 20%.[3] Non–US-born persons had a TB rate 15.5 times greater than the rate among US-born persons.[3] These disparities are the result of a complex interplay of social and environmental factors including urbanization, access to healthcare, poverty, and migration.[3,4]

In 2019, the number of TB cases was highest in the 25- to 44-year and the 45- to 64-year-age groups, while the rate per 100,000 population was highest in those over 65 years of age.[3] The overall TB incidence was 2.7 per 100,000 population.[3]

Coinfection with Human Immunodeficiency Virus

③ In patients who have LTBI, human immunodeficiency virus (HIV) is the most important risk factor, especially for people between the ages of 25 and 44 years.[4] TB and HIV act synergistically within patients and across populations, making each disease worse than it might otherwise be. In 2019, 4.9% of TB patients with known HIV statues were coinfected, with about 7.8% in the 25- to 44-year age group.[3,4,5] HIV coinfection may not increase the risk of acquiring *M. tuberculosis* infection, but it does increase the likelihood of progression to active disease.[4] There are higher mortality rates in persons coinfected with HIV and MDR or and extensively drug-resistant (XDR) TB.[5]

Risk Factors for Disease

Once infected with *M. tuberculosis*, a person's lifetime risk of active TB is approximately 10%.[2–4] The greatest risk for active disease occurs during the first 2 years after infection. Children younger than 2 years and adults older than 65 years have two to five times greater risk for active disease compared with other age groups. Patients with underlying immune suppression (eg, renal failure, cancer, and immunosuppressive drug treatment) have 4 to 16 times greater risk than other patients.[5] HIV-infected patients with *M. tuberculosis* infection are 100 times more likely to develop active TB than normal hosts.[5] HIV-infected patients have an annual risk of active TB of approximately 10%, rather than a lifetime risk at that rate.[5] Therefore, all patients with HIV infection should be screened for TB infection, and those known to be infected with *M. tuberculosis* should be tested for HIV infection.

ETIOLOGY

M. tuberculosis is a slender bacillus with a waxy outer layer.[6] It is 1 to 4 μm in length, and under the microscope, it is either straight or slightly curved in shape.[6] It does not stain well with Gram stain, so the Ziehl–Neelsen stain or the fluorochrome stain must be used instead.[6] After Ziehl–Neelsen staining with carbol-fuchsin, mycobacteria retain the red color despite acid–alcohol washes. Hence, they are called *acid-fast bacilli* (AFB).[6] On culture, *M. tuberculosis* grows slowly, doubling about every 20 hours. This is slow compared with gram-positive and gram-negative bacteria, which double about every 30 minutes.

Culture and Susceptibility Testing

All clinical specimens suspected of containing mycobacteria should be cultured. Culture is required for species identification and for drug-susceptibility testing.

4 Direct susceptibility testing involves inoculating specialized media with organisms taken directly from a concentrated, smear-positive specimen.[6] This approach produces susceptibility results in 2 to 3 weeks. Culture-based phenotypic drug-susceptibility testing methods are the primary methods for drug-resistance detection. These methods are time consuming and require sophisticated laboratory infrastructure. Direct susceptibility testing uses critical concentrations of antituberculosis drugs to determine resistance of an isolate. A critical concentration is a previously established breakpoint separating “susceptible” from “resistant.” Indirect susceptibility testing involves inoculating the test media with organisms obtained from a pure culture of the organisms, which can take several more weeks.[1,6]

The most common agar method has limitations which include length of time to obtain results, drug degradation during incubation, and a qualitative result (susceptible or resistant). The newer mycobacterial growth indicator tube (MGIT, Becton Dickson, Sparks, MD) systems use liquid media and detect live mycobacteria in as few as 9 to 14 days.[7,8]

Rapid identification tests are now available, but cost and care of equipment remain an issue in many parts of the world.[6–9] The Enhanced Amplified *Mycobacterium tuberculosis* Direct test has been approved for use by the US Food and Drug Administration (FDA) in AFB smear-positive and smear-negative specimen in patients with fewer than 7 days of antimycobacterial therapy and the Gene Xpert MTB/RIF assay in patients with fewer than 3 days of treatment.[9–11] The Amplicor *Mycobacterium tuberculosis* test has been approved for smear-positive samples.[7,8]

The Hain test, a line-probe assay that diagnoses resistance to isoniazid and rifampin by detecting several gene mutations responsible for drug resistance, has also entered into limited clinical use in the United States.[8] The Gene X-pert MTB/RIF test simultaneously identifies *M. tuberculosis* and rapidly determines if resistance to rifampin is present.[9–11] The test has excellent performance in both smear-positive and -negative patients, and high accuracy for determination of rifampicin resistance.[9,11] Colorimetric redox indicator and nitrate reduction assays for rapid detection of rifampicin and isoniazid resistance are both inexpensive and have rapid turnaround times of 1 week. Microscopic observation drug-susceptibility assay is simple test using sputum samples to detect characteristic patterns of growth of *M. tuberculosis* and resistance patterns.[9,11] Time to diagnosis is 7 days and drug susceptibilities are available at the time of diagnosis.[11] Most patients with microscopic observation drug-susceptibility assays are diagnosed within 2 weeks, and it is similarly efficient irrespective of bacterial burden.[12]

Other tests are designed to detect common genetic changes associated with drug resistance, such as changes in the *katG* gene associated with isoniazid resistance and the *rpoB* gene associated with rifampin resistance.[8,13] Mutations that affect the *rpoB* gene alter the protein structure of the target so that rifampin cannot bind; thus, conferring resistance. Similarly, isoniazid-resistant isolates can be detected by sequencing the *inhA* gene which leads to overproduction of the drug target and mutations in *katG* gene which inhibits activation of isoniazid prodrug. Probe assays do not eliminate the need for conventional culture and susceptibility testing; conventional drug-susceptibility testing is needed to diagnose XDR-TB. The decision to use nucleic acid amplification tests should be individualized.[8,13] Advanced sequencing techniques continue to evolve.

Transmission

M. tuberculosis is transmitted from person to person by coughing or other activities that cause the organism to be aerosolized.[14] These particles, called *droplet nuclei,* contain one to three bacilli and are small enough (1-5 mm) to reach the alveolar surface.[15] Approximately 30% of individuals who experience prolonged contact with an infectious TB patient will become infected.[14]

A person with cavitary, pulmonary TB and a cough is considered infectious and may infect greater than 30% of contacts until that person is treated effectively, although this percentage and the absolute number can vary significantly. A person with the uncommon laryngeal form of TB can spread organisms even when talking, so the transmission rates can be even higher.[14,15]

The National TB Molecular Surveillance Center performs whole genome sequencing on isolates of *M. tuberculosis* gathered from newly diagnosed patients in the United States. Samples are submitted by contracted laboratories and then genotype results are loaded into the system to identify chains of transmission and outbreaks.[8] Public health interventions can be targeted and cases that are the same cluster are likely to be related and treated similarly.[8]

PATHOPHYSIOLOGY

Immune Response

T-lymphocyte responses are essential to controlling *M. tuberculosis* infections.[14,15] In the mouse model, two different T-cell responses—the T-helper type 1 (TH_1) response and the T-helper type 2 (TH_2) response—have been described. The TH_1 response is the preferred response to TB, and the TH_2 response, including the potentially subversive influence of interleukin (IL) 4, is undesirable.[14,15] This dichotomy is clearer in the mouse model, and in many humans, the T-cell response may be classified as TH_0 (elements of both TH_1 and TH_2).[14,15] In either case, T lymphocytes activate macrophages that, in turn, engulf and kill mycobacteria. T lymphocytes also destroy immature macrophages that harbor *M. tuberculosis* but are unable to kill the invaders.[14,15] CD4+ cells are the primary T cells involved, with contributions by γ δ T cells and CD8+ T cells.[14] CD4+ T cells produce INF-*γ* and other cytokines, including IL-2 and IL-10, that coordinate the immune response to TB.[14,15] Because CD4+ cells are depleted in HIV-infected patients, these patients are unable to mount an adequate defense to TB.[14,15]

Although B-cell responses and antibody production can be demonstrated in TB-infected mammals, these humoral responses may not contribute much to the control of TB within the host.[15] Tumor necrosis factor-*α* (TNF-*α*) and INF-*γ* are important cytokines involved in coordinating the host's cell-mediated response.[16] Rheumatoid arthritis patients treated with TNF-*α* inhibitors (such as infliximab) have high rates of reactivation TB.[16] Therefore, patients deficient in the activity of TNF-*α* or INF-*γ* should be screened for TB infection and offered appropriate treatment.

M. tuberculosis has several ways of evading or resisting the host immune response.[15] In particular, *M. tuberculosis* can inhibit the fusion of lysosomes to phagosomes inside macrophages, preventing the destructive enzymes found in the lysosomes from getting to the bacilli captured in the phagosomes. This inhibition of destructive mechanisms allows time for *M. tuberculosis* to escape into the cytoplasm. Virulent *M. tuberculosis* bacilli are able to multiply in the macrophage cytoplasm, thus perpetuating their spread. Finally, lipoarabinomannan (LAM), the principal structural polysaccharide of the mycobacterial cell wall, inhibits the host immune response.[15] LAM induces immunosuppressive cytokines, thus blocking macrophage activation; additionally, LAM scavenges O_2, thus preventing attack by superoxide anions, hydrogen peroxide, singlet oxygen, and hydroxyl radicals.[15] These survival mechanisms make *M. tuberculosis* a particularly difficult organism to control. Any defects in the host immune system make it likely that *M. tuberculosis* will not be controlled and that active disease will ensue.

Primary Infection

Primary infection usually results from inhaling airborne particles that contain *M. tuberculosis*.[15,17] The progression to clinical disease depends on three factors: (a) the number of *M. tuberculosis* organisms inhaled (infecting dose), (b) the virulence of these organisms, and (c) the host's cell-mediated immune response.[15,17] At the alveolar surface, the bacilli that were delivered by the droplet nuclei are ingested by pulmonary macrophages. If these macrophages inhibit or kill the bacilli, infection is aborted.[15] If the macrophages cannot do this, the organisms continue to multiply. The macrophages eventually rupture, releasing many bacilli, and these mycobacteria are then phagocytized by other macrophages. This cycle continues over several weeks until the host is able to mount a more coordinated response.[15,17] During this early phase of infection, *M. tuberculosis* multiplies logarithmically.[15]

Some of the intracellular organisms are transported by the macrophages to regional lymph nodes in the hilar, mediastinal, and retroperitoneal areas. The cycle of phagocytosis and cell rupture continues. During lymph node involvement, the mycobacteria may be held in check. More frequently, *M. tuberculosis* spreads throughout the body through the bloodstream.[14,15] When this intravascular dissemination occurs, *M. tuberculosis* can infect any tissue or organ in the body. Most commonly, *M. tuberculosis* infects the posterior apical region of the lungs. This may be so because of the high oxygen content or less vigorous immune response in this area.[14,17]

After about 3 weeks of infection, T lymphocytes are presented with *M. tuberculosis* antigens. These T cells become activated and begin to secrete INF-*γ* and the other cytokines noted earlier. The processes described in the "Immune Response" section above then begin to occur.[14] First, T lymphocytes stimulate macrophages to become bactericidal.[14,15] Large numbers of activated microbicidal macrophages surround the solid caseous (cheese-like) tuberculous foci (the necrotic area of infection).[14,15] This process of creating activated microbicidal macrophages is known as cell-mediated immunity.[15]

When cell-mediated immunity occurs, delayed-type hypersensitivity (DTH) also develops through the activation and multiplication of T lymphocytes. DTH refers to the cytotoxic immune process that kills nonactivated immature macrophages that are permitting intracellular bacillary replication.[15] These immature macrophages are killed when the T lymphocytes initiate Fas-mediated apoptosis (programmed cell death).[15] The bacilli released from the immature macrophages then are killed by the activated macrophages.[15]

After 3 weeks, in most recently infected individuals, macrophages have begun to form granulomas to contain the organisms. In a typical tuberculous granuloma, activated macrophages accumulate around a caseous lesion and prevent its further extension.[15] At this point, the infection is largely under control, and bacillary replication falls off dramatically. Depending on the inflammatory response, tissue necrosis and calcification of the infection site plus the regional lymph nodes may occur.

Over 1 to 3 months, activated lymphocytes reach an adequate number, and tissue hypersensitivity results. In practical terms, this is the reason why tests to diagnose LTBI, purified protein derivative (PPD) skin test, and the INF-γ release assays take between 2 and 12 weeks to become positive. Any remaining mycobacteria are believed to reside primarily within granulomas or within macrophages that have avoided detection and lysis, although some residual bacilli have been found in various types of cells.[6,14]

Approximately 90% of infected patients have no further clinical manifestations. Most patients only show a positive skin or blood test for immune response (70%), whereas some also have radiographic evidence of stable granulomas.[17] This radiodense area on chest radiograph is called a *Ghon's complex*. Approximately 5% of patients (usually children, older adults, and the immunocompromised) experience "progressive primary" disease that occurs before skin test conversion, which presents as a progressive pneumonia, usually in the lower lobes.[17] Disease frequently spreads, leading to meningitis and other severe forms of TB.[17,18] Because of this risk of severe disease, young, elderly, and immunocompromised patients, including those with HIV, should be evaluated and treated for latent or active TB.[17,18]

Reactivation Disease

⑥ Roughly 10% of infected patients develop reactivation disease at some point in their lives. Nearly half of these cases occur within 2 years of infection.[14,17] In the United States, most cases of TB result from reactivation. Reinfection is uncommon in the United States because of the low rate of exposure and because previously sensitized individuals possess some degree of immunity to reinfection.[14,17] Exceptions include patients coinfected with HIV who live in areas of higher exposure to *M. tuberculosis*.

The apices of the lungs are the most common sites for reactivation (85% of cases).[14,17] For reasons that are not entirely known (waning cellular immunity, loss of specific T-cell clones, blocking antibody), organisms within granulomas emerge and begin multiplying extracellularly.[14,17] The inflammatory response produces caseating granulomas, which eventually will liquefy and spread locally, leading to the formation of a hole (cavity) in the lungs.

The immune response contributes to the severity of the lung damage, and DTH allows for intracellular mycobacterial multiplication.[14,15] In addition, there is "innocent bystander" killing of host cells and locally thrombosed blood vessels.[14] The killing of mycobacteria, macrophages, and neutrophils that have entered the battle releases cytokines and lysozymes into the infectious foci. This toxic mixture can be too much for the surrounding alveoli and airway cells, causing regional necrosis and structural collapse.[14] These unstable foci liquefy, spreading the infection to neighboring areas of the lung, creating a cavity. Some of this necrotic material is coughed out, producing droplet nuclei. Bacterial counts in the cavities can be as high as 10^8 per milliliter (or 10^{11}/L) of cavitary fluid. Partial healing may result from fibrosis, but these lesions remain unstable and may continue to expand.[14] If left untreated, pulmonary TB continues to destroy the lungs, resulting in hypoxia, respiratory acidosis, and eventually death.

Extrapulmonary and Miliary Tuberculosis

Caseating granulomas at extrapulmonary sites can undergo liquefaction, releasing tubercle bacilli and causing symptomatic disease.[14] Extrapulmonary TB without concurrent pulmonary disease is uncommon in normal hosts but more common in HIV-infected patients. Because of these unusual presentations, the diagnosis of TB is difficult and often delayed in immunocompromised hosts.[14] Lymphatic and pleural diseases are the most common forms of extrapulmonary TB, followed by bone, joint, genitourinary, meningeal, and other forms.[14] Occasionally, a massive inoculum of organisms enters the bloodstream, causing a widely disseminated form of the disease known as *miliary TB*. It is named for the millet seed appearance of the small granulomas seen on chest radiographs, and it can be rapidly fatal.[14] Miliary TB is a medical emergency requiring immediate treatment.

Influence of Human Immunodeficiency Virus Infection on Pathogenesis

③ HIV infection is the strongest single risk factor for progressing to active TB.[14,17] As CD4+ lymphocytes multiply in response to the mycobacterial infection, HIV multiplies within these cells and selectively destroys them. In turn, the TB-fighting lymphocytes are depleted.[14,17] This vicious cycle puts HIV-infected persons at 100 times the risk of active TB compared with HIV-negative people.[19,20] In addition, the combination of HIV infection and certain social behaviors increases the risk of newly acquired TB. In select areas of the United States during the resurgence of TB during the early 1990s, up to 50% of new TB cases were the result of recent infection, particularly among HIV-infected individuals.[1,19,20]

As mycobacteria spread throughout the body, HIV replication accelerates in lymphocytes and macrophages. This leads to progression of HIV disease.[14,19,20] HIV-infected persons who are infected with TB deteriorate more rapidly unless they receive antimycobacterial chemotherapy.[19,20] Most clinicians now recommend integrated antiretroviral therapy beginning TB treatment first, and then beginning HIV treatment within 2 to 12 weeks.[21–23] However, the timing needs to be individualized based on degree of immunosuppression from HIV and the individual's tolerance of the treatment regimen. Immune reconstitution inflammatory syndrome or a paradoxical worsening of TB can occur, especially in persons with more severe immunosuppression; this results from a reinvigorated inflammatory response to TB.[21,23] HIV-positive persons should be screened for tuberculous infection or disease soon after they are shown to be HIV positive.[21]

CLINICAL PRESENTATION

The classical presentation of TB is weight loss, fatigue, a productive cough, fever, and night sweats. The onset of TB may be gradual, and the diagnosis may not be considered until a chest radiograph is performed. Unfortunately, many people do not seek medical attention until more dramatic symptoms, such as hemoptysis, occur. At this point, infected persons typically have large cavitary lesions in the lungs. These cavities are loaded with *M. tuberculosis*. Expectoration or swallowing of infected sputum may spread the disease to other areas of the body.[14,17,24] Physical examination is nonspecific but can be suggestive of progressive pulmonary disease.

Human Immunodeficiency Virus

⑤ Persons coinfected with HIV may have atypical presentations.[19–21,24] As their CD4+ counts decline, HIV-positive individuals are less likely to have positive skin tests, cavitary lesions, or fever. Pulmonary radiographic findings may be minimal or absent. HIV-positive persons have a higher incidence of extrapulmonary TB and are more likely to present with progressive primary disease. Because their symptoms are not specific to TB, a thorough workup for TB is essential.[20,21]

Extrapulmonary

Extrapulmonary TB typically presents as a slowly progressive decline in organ function.[14,17–19] Infected persons may have low-grade fever and other constitutional symptoms. Those with genitourinary TB may present with sterile pyuria and hematuria. Lymphadenitis often involves the cervical and supraclavicular nodes and may appear as a neck mass with spontaneous drainage. Tuberculous arthritis and osteomyelitis occur most commonly in the older adults and usually affect the lower spine and weight-bearing joints. TB of the spine is known as *Pott's disease*.[14] Abnormal behavior, headaches, or convulsions suggest tuberculous meningitis. Involvement of the peritoneum, pericardium, larynx, and adrenal glands also occurs.[14,18]

Older Adults

⑤ TB in the older adults is easily confused with other respiratory diseases. Many clinical findings are muted or absent altogether. Compared with younger patients, TB in the older adults is far less likely to present with positive skin tests, fevers, night sweats, sputum production, or hemoptysis.[14,17,24] Weight loss may occur but is nonspecific. In contrast, mental status changes are twice as common in older adults, and mortality is six times higher.[14,17] TB is a preventable cause of death in older adults that should not be overlooked.

Children

⑤ TB in children, especially those younger than 12 years, may present as a typical bacterial pneumonia and is called *progressive primary TB*.[17,18,24]

Clinical disease often begins 1 to 2 months after exposure and precedes skin-test positivity. Unlike adults, pulmonary TB in children often involves the lower and middle lobes.[17,18] Dissemination to the lymph nodes, gastrointestinal (GI) and genitourinary tracts, bone marrow, and meninges is common. Because of delays in recruitment of cellular immunity, cavitary disease is infrequent, and the number of organisms present typically is smaller than in an adult. Because cavitary lesions are uncommon, children do not spread TB readily. However, TB can be rapidly fatal in a child, and it requires prompt chemotherapy.

CLINICAL PRESENTATION: Tuberculosis

Signs and Symptoms

- Patients typically present with cough weight loss, fatigue, fever, and night sweats.[2,14,15]
- Frank hemoptysis usually occurs late in the course of disease but may present earlier.

Physical Examination

- Dullness to chest percussion, rales, and increased vocal fremitus are observed frequently on auscultation but a normal lung examination is common compared to the degree of radiological lung involvement.
- Patient is usually thin with evidence or recent weight loss.

Laboratory Tests

- Moderate elevations in the white blood cell count with a lymphocyte predominance.
- High platelet count (thrombocytosis) and mild-to-moderate anemia are common.

Diagnostic Considerations

- Positive-sputum smear
- Fiber-optic bronchoscopy (if sputum tests are inconclusive and suspicion is high)

Chest Radiograph

- Patchy or nodular infiltrates in the apical areas of the upper lobes or the superior segment of the lower lobes.[2,14,15]
- Cavitation that may show air–fluid levels as the infection progresses.

DIAGNOSIS

The following section focuses on diagnostic testing for infection with *M. tuberculosis*. If active disease is suspected based on clinical presentation, additional diagnostic tests are also reviewed to confirm active disease.

Diagnostic Testing

The key to stopping the spread of TB is early identification of infected individuals.[24] Table 135-1 lists the populations most likely to benefit from testing (column 1 persons are at highest risk for TB, followed by those in column 2). Members of these high-risk groups should be tested for TB infection and educated about the disease.

TABLE 135-1

Criteria for Tuberculosis Positivity

Reaction ≥5 mm of Induration	Reaction ≥10 mm of Induration	Reaction ≥15 mm of Induration
HIV-infected persons A recent contact of a person with TB disease Fibrotic changes on chest radiograph consistent with prior TB Patients with organ transplants and other immunosuppressed patients (receiving the equivalent of 15 mg/day or more of prednisone for 1 month or longer, taking TNF-α antagonists)[b]	Recent immigrants (ie, within the last 5 years) from high-prevalence countries Injection drug users Residents and employees[a] of the following high-risk congregate settings: prisons and jails, nursing homes and other long-term facilities for the elderly, hospitals and other healthcare facilities, residential facilities for patients with AIDS, and homeless shelters Mycobacteriology laboratory personnel, persons with the following clinical conditions that place them at high risk: silicosis, diabetes mellitus, chronic renal failure, some hematologic disorders, other specific malignancies, gastrectomy, and jejunoileal bypass Children younger than 5 years of age or infants, children, and adolescents exposed to adults at high risk	Persons with no risk factors for TB
Interpretation of IGRA Results		
The interpretation of IGRAs is based on the amount of IFN-γ, in T-SPOT®.TB. An IGRA is recommended over a TST in persons at least 5 years of age who are likely to have *M. tuberculosis* infection; who are at low or moderate risk of the disease progressing; in whom it has been determined that LTBI testing is necessary; and who have been vaccinated against Calmette-Guerin or are not likely to return for follow up after a TST. The TST is a viable second option in certain circumstances, such as if an IGRA is unavailable. Laboratories should provide both the qualitative and quantitative results. • Qualitative results are reported positive, negative, indeterminate, or borderline. • Quantitative results are reported as numerical values that include a response to the TB antigen and two controls, nil and mitogen. • Quantitative results may be useful for clinical decision making in individual cases, in combination with risk factors.		

[a] For persons who are otherwise at low risk and who are tested at the start of employment, a reaction of ≥15 mm induration is considered positive.

[b] Risk of TB for patients treated with corticosteroids increases with higher dose and longer duration.

AIDS, acquired immunodeficiency syndrome; TST, tuberculin skin tests.

Data from Centers for Disease Control and Prevention. Screening for tuberculosis and tuberculosis infection in high-risk populations: recommendations of the Advisory Council for the Elimination of Tuberculosis. M.M.W.R. 1995;44(No. RR-11):19–34.

The Mantoux test is a quantitative TB skin test that uses tuberculin PPD. The standard 5-tuberculin-unit PPD dose is placed intracutaneously on the volar aspect of the forearm with a 26- or 27-gauge needle.[24,25] This injection should produce a small, raised, blanched wheal. An experienced professional should read the test in 48 to 72 hours. The area of induration (the "bump") is the important end point, not the area of redness. Table 135-1 lists the criteria for interpretation.[24,25] The Centers for Disease Control and Prevention (CDC) does not recommend the routine use of anergy panels.[24–27] Aplisol and tubersol 5-tuberculin-unit products are available commercially and are similar in sensitivity, specificity, and reactivity. It is important, however, to use one product and notify appropriate users when switching between products.[27]

The "booster effect" occurs for persons who do not respond to an initial skin test but show a positive reaction if retested about a week later or longer.[17,28] Persons with past *M. tuberculosis* infection and some with past immunization with bacillus Calmette-Guérin (BCG) vaccine or past infection with other mycobacteria may "boost" with a second skin test. Individuals who require periodic skin testing, such as healthcare workers, should receive a two-stage test initially.[17,28] Once they are shown to be skin-test negative, any positive skin test later shows recent infection, and this requires an evaluation to consider treatment.

The PPD skin test is an imperfect diagnostic tool. Up to 20% of persons with active TB are falsely skin-test negative, presumably because they may be immunocompromised.[25,26] False-positive results are more common in low-risk patients and those recently vaccinated with BCG. Despite BCG vaccination, one should not ignore a positive PPD result especially if the induration is more than 15 mm.[24] These individuals require careful evaluation for active disease, and they may be offered preventive treatment because many come from areas where TB infection is common.

Interferon-γ release assays (IGRA) measure the release of INF-γ in blood in response to the TB antigens.[29] They may provide quick and specific results for identifying *M. tuberculosis*. IGRAs do not trigger a booster effect and are more specific for testing *M. tuberculosis* than the PPD. The QuantiFERON-TB Gold test is an enzyme-linked immunosorbent assay and the T-SPOT.®TB is an enzyme-linked immunospot assay.[29] Both tests can be used for diagnosing LTBI and TB disease caused by *M. tuberculosis*. However, these are the tests designed to diagnose LTBI and are not to be used to confirm or reject a diagnosis of active TB disease. For active TB, the IGRAs provide supporting evidence for the diagnosis but need to be interpreted in light of other evidence of active TB disease such as epidemiological risk factors and other studies. The antigenic proteins are absent from BCG vaccine strains and from most non-TB mycobacteria. Therefore, QuantiFERON-TB Gold test does not trigger a booster effect and is more specific for testing of *M. tuberculosis* than the PPD. Although these tests can provide results to diagnose both latent infection and disease, they cannot differentiate between the two. Results are available within 24 hours, instead of the 2 to 3 days required for the traditional PPD skin test; and the patient does not have to return to the clinic as required by the PPD skin test. The CDC has approved the use of these tests in all circumstances in which the PPD is used. IGRAs may be preferred for testing in patients who are suspected not to return for follow-up PPD reads or in patients who have received the BCG vaccine.[29] IGRA is recommended over a TST or PPD in individuals 5 years or older who meet the following criteria: (1) are likely to be infected with *M. tuberculosis*, (2) have a low-to-intermediate risk of disease progression, (3) testing for LTBI is warranted, (4) history of BCG vaccination, and (5) are unlikely to return to have their PPD read.[29] IGRA rather than PPD is also suggested in all other individuals who are likely to be infected with *M. tuberculosis*, who have a low-to-intermediate risk of disease progression, and in whom testing for LTBI is warranted.[29] There are insufficient data to recommend a preference for either a PPD or IGRA as the first-line diagnostic test in patients likely to be infected with *M. tuberculosis*, who have a high risk of progression to disease, and in whom diagnostic testing is warranted.[29] Figure 135-2 summarizes the recommendations for testing for latent tuberculosis infections (LTBI).

FIGURE 135-2

Summary of recommendations for testing for latent tuberculosis infection (LTBI).

[a]Performing a second diagnostic test when the initial test is a negative is a strategy to increase sensitivity. This may reduce specificity, but the panel decided that this is an acceptable trade off in situations in which the consequences of missing LTBI exceed the consequences of inappropriate therapy. [b]Performing a confirmatory test following an initial positive result is based upon both the evidence that false positive results are common among individuals who are unlikely to be infected with *Mycobacterium tuberculosis* and the committee's presumption that performing a second test on those patients whose initial test was positive will help identify initial false positive results. *(Adapted from Lewinsohn DM, Leonard MK, LoBue PA, et al. Official American Thoracic Society/Infectious Diseases Society/Centers for Disease Control and Prevention clinical practice guidelines: diagnosis of tuberculosis in adults and children. 2017;64:e1–e11.)*

The sensitivity for young children (younger than 5 years) and in immunocompromised individuals has not been clearly established.[30–32] A PPD test is recommended in healthy children (younger than 5 years) for who diagnostic testing is warranted. The American Academy of Pediatrics recommends IGRAs in place of PPD skin test in immunocompetent children aged 5 years or older who have received BCG vaccination to confirm TB infection.[31] However, an increasing number of experts are using the IGRAs in children 3 years or older.

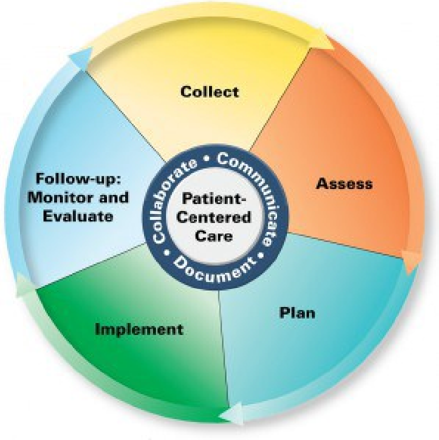
IGRAs perform similarly to the PPD in detecting TB in HIV-infected persons with LTBI. Both PPD and IGRA have suboptimal sensitivity for active TB especially in the severely immunocompromised.[33,34]

Culture and Staining

When active TB is suspected, attempts should be made to isolate *M. tuberculosis* from the site of infection.[17,24] Sputum collected in the morning usually has the highest yield.[17,24] Daily sputum collection over three consecutive days is recommended. Microscopic examination is the most rapid and inexpensive TB diagnostic tool. After staining, microscopic examination ("smear") detects about 8,000 to 10,000 organisms per milliliter (8 × 10^6/L to 10 × 10^6/L) of specimen, so a patient can be "smear-negative" but still grow *M. tuberculosis* on culture. Microscopic examination also cannot determine which of the more than 150 mycobacterial species is present or whether the organisms in the original samples were alive or dead.[17,24]

For persons unable to expectorate, sputum induction with aerosolized hypertonic saline may produce a diagnostic sample. Bronchoscopy, in older children, or aspiration of gastric fluid via a nasogastric tube, in children (5 years or younger), may be attempted for select individuals.[17] For persons with suspected extrapulmonary TB, samples of draining fluid, biopsies of the infected site, or both may be attempted. Blood cultures are positive occasionally, especially in persons with acquired immunodeficiency syndrome (AIDS).[17,19]

Patient Care Process for Active Tuberculosis



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, ethnicity)
- Patient medical history (medical risk factors, eg, immunocompromised, HIV, tobacco/ethanol/IV drug use)
- Social history (eg, living conditions, recent contacts)
- Current medications including prescription and nonprescription medicines, herbal products
- Information and history about patients adherence to medications
- History of clinical signs and symptoms (weight loss, cough, hemoptysis)
- Objective data
    - Sputum smears/culture
    - Chest x-ray
    - Tuberculin skin test (TST)/Interferon-γ (INF-γ) release assays
    - Pertinent labs (white blood cell, platelets, serum creatinine, LFTs)

Assess

- Patient's potential for risk of transmission
- Risk of mycobacterial resistance

- Risk of drug malabsorption/drug interactions
- Need for therapeutic drug monitoring
- Immune status
- Ability/willingness to be adherent to prescribed regimen
- Psychological status to determine understanding and following instructions for adherence; need for directly observed therapy
- Ability/willingness to maintain follow-up

Plan[*]

- Devise a drug-therapy regimen with healthcare team to include most appropriate antituberculosis agents, dose, route, frequency, and duration (see Tables 135-3 and 135-4)
- Monitoring parameters including efficacy (eg, sputum smears) and safety (eg, LFTs, neuropathy); frequency and timing of follow-up (see Table 135-8)
- Patient education (eg, purpose of treatment, infection control, drug-specific information, importance of compliance/legal ramifications and risk of noncompliance)

Implement

- Provide patient education regarding all elements of treatment plan and goals
- Ensure patient understanding of risk of transmission and importance of adherence
- Schedule follow-up (eg, adherence assessment, adverse effects, response to treatment)

Follow-Up: Monitor and Evaluate

- Monthly clinic evaluation
- Objective data
    - Sputum smears
    - Chest x-ray results
    - Pertinent labs
- Determine response to therapy
    - Clinical response (cough, fever, night sweats)
    - Culture results
- Need for therapeutic drug monitoring
- Presence of adverse effects
- Patient adherence to treatment plan
    - Tablet/Capsule counts for compliance or attending directly observed treatment.

[*] *Collaborate with patients, caregivers, and other healthcare professionals.*

TREATMENT

Drugs used in the treatment of active disease are divided into first-line and second-line agents. First-line agents should be the preferred options unless susceptibility results dictate otherwise. Treatment in special populations is also addressed.

Desired Outcome

The primary desired outcomes during the treatment of TB are:

1. Rapid identification of a new TB case.
2. Initiation of specific antituberculosis treatment.
3. Eradication of *M. tuberculosis* infection.
4. Achievement of a noninfectious state in the patient, thus ending isolation.
5. Prevention of the development of resistance.
6. Adherence to the treatment regimen by the patient.
7. Cure of the patient as quickly as possible (generally at least 6 months of treatment).

Patients with active disease should be isolated to prevent spread of the disease, and appropriate samples for smears and cultures should be collected. Secondary goals are identification of the index case that infected the individual, identification of all persons infected by both the index case and the new case of TB (“contact investigation”), and completion of appropriate treatments for those individuals.

General Approaches

Drug treatment is the cornerstone of TB management.[35] Monotherapy can be used only for infected persons who do not have active TB (latent infection, as shown by a positive skin test or positive IGRA). Once active disease is present, most patients receive four drugs.[35] The duration of treatment depends on the condition of the host, extent of disease, presence of drug resistance, and tolerance of medications. Most patients are treated for 6 months, and 18 to 24 months of treatment may be necessary for cases of MDR-TB.[35] Because the duration of treatment is so long and because many individuals feel better after a few weeks of treatment, careful follow-up is required. Directly observed therapy (DOT) by a healthcare worker is a cost-effective way to ensure completion of treatment and is considered the standard of care.[36,37]

Principles for Treating Latent Infection and for Treating Disease

Asymptomatic patients with tuberculous infection have a bacillary load of about 10^3 organisms, compared with 10^{11} organisms in a patient with cavitary pulmonary TB.[14] As the number of organisms increases, the likelihood of naturally occurring drug-resistant mutants also increases. Naturally occurring mutants that are resistant to antituberculosis drugs are found at rates of 1 in 10^6 to 1 in 10^8 organisms.[13] When treating asymptomatic latent infection with monotherapy, the risk of selecting out resistant organisms is low. In contrast, the risk of selecting out isoniazid-resistant organisms is unacceptably high for patients with cavitary TB. One can prevent selection of these resistant mutants by adding more drugs because the rates for resistance mutations to multiple drugs are additive functions of the individual rates. For example, only 1 in 10^{13} organisms would be naturally resistant to both isoniazid (1 in 10^6) and rifampin (1 in 10^7).[13,35] It is unlikely that such rare organisms are present in a previously untreated patient.

Combination chemotherapy is required for treating active TB disease. Generally, four drugs are given at the outset of treatment. Of the most commonly used four drugs, rifampin and isoniazid are the best drugs for preventing resistance.[38]

Three subpopulations of mycobacteria are proposed to exist within the body, and each appears to respond to certain drugs.[35,38] Most numerous are the extracellular, rapidly dividing bacteria, often found within cavities (about 10^7-10^9 so-called “log phase” organisms). These are killed most readily by isoniazid, followed by rifampin.[38,39] A second group resides within caseating granulomas (possibly 10^5-10^7 organisms). These organisms appear to be in a semidormant state, with occasional bursts of metabolic activity. Pyrazinamide, through its conversion within *M. tuberculosis* to pyrazinoic acid, appears most active against these so called “acid phase” organisms. The third subset is the intracellular mycobacteria present within macrophages (10^4-10^6) and other “non-replicating persisters.”[39] Rifampin, bedaquiline, and pretomanid, appear to be most active against these “nonreplicating” persisters. While this model explains what happens during the treatment of TB, there is no practical way to quantitate these mycobacterial subpopulations within a given patient.

Nonpharmacologic Therapy

⑦ Nonpharmacologic interventions aim to: (a) prevent the spread of TB, (b) find where TB has already spread using contact investigation, and (c) replenish the weakened (consumptive) infected person to a state of normal weight and well-being. The first two items are performed by public health departments. Clinicians involved in the treatment of TB should verify that the local health department has been notified of all new cases of TB.

Workers in hospitals and other institutions must prevent the spread of TB within their facilities.[28] All such workers should learn and follow each institution’s infection control guidelines. This includes using personal protective equipment, including properly fitted respirators, and closing doors to “negative-pressure” rooms. These hospital isolation rooms draw air in from surrounding areas rather than blowing air (and *M. tuberculosis*) into these surrounding areas. The air from the isolation room may be treated with ultraviolet lights and then vented safely outside. However, these isolation rooms work properly only if the door is closed.

Debilitated persons infected with TB may require therapy for other medical problems, including substance abuse and HIV infection, and some may need nutritional support. Therefore, clinicians involved in substance abuse rehabilitation and nutritional support services should be familiar with the needs of persons infected with TB. Surgery may be needed to remove destroyed lung tissue, space-occupying infected lesions (*tuberculomas*), and certain extrapulmonary lesions.[24] BCG is the only clinically relevant vaccine for TB in use today. Although it is one of the most commonly administered vaccines in history, it is of limited value, and cannot prevent infection by *M. tuberculosis*. BCG (discussed further) may prevent extreme forms of TB in infants.[24]

Pharmacologic Therapy

Treating Latent Infection

The treatment of LTBI has been called *prophylaxis*. The keys to successful treatment of LTBI are: (a) infection by a drug-susceptible isolate, (b) adherence to the regimen, and (c) no exogenous reinfection.[40] Table 135-2 lists the first-line treatment options for latent tuberculosis.

TABLE 135-2

Doses Recommended for Latent Tuberculosis Treatment Regimens

Drug	Duration	Dose
Isoniazid and rifapentine	Once weekly for 3 months	Adults and children 12 years: Isoniazid: 15 mg/kg Rifapentine: 10-14 kg: 300 mg 14.1-25 kg: 450 mg 25.1-32 kg: 600 mg 32.1-49.9 kg: 750 mg ≥50kg: 900 mg Children 2-11 years: Isoniazid: 25 mg/kg Rifapentine: see above
Isoniazid and rifampin	Daily for 3 months	Adult: Isoniazid: 5 mg/kg Rifampin: 10 mg/kg Children: Isoniazid: 10-20 mg/kg Rifampin: 15-20 mg/kg
Rifampin	Daily for 4 months	Adults: 10 mg/kg Children: 15-20 mg/kg

Data from Sterling TR, Njie G, Zenner D, et al. Guidelines for the Treatment of Latent Tuberculosis Infection: Recommendations from the National Tuberculosis Controllers Association and CDC, 2020. MMWR Recomm Rep. 2020;69:1.

Because young children, older adults, and HIV-positive persons are at greater risk of active disease once infected with *M. tuberculosis*, they require careful evaluation. Once active TB is ruled out, they should receive treatment for latent infection.[40]

There are three recommended treatment regimens for LTBI: 3 months of once-weekly isoniazid plus rifapentine; 4 months of daily rifampin or 3 months of daily isoniazid plus rifampin. Table 135-2 outlines recommended starting doses. The CDC recommends the 12-week isoniazid/rifapentine regimen as an equal alternative to 9 months of daily isoniazid for treating LTBI in otherwise healthy patients aged 12 years or older who have a predictive factor for a greater likelihood of developing active TB. These include recent exposure to contagious TB, conversion from negative to positive on an indirect test for infection (ie, IGRA or TST), radiographic findings of healed pulmonary TB, and untreated HIV infection.[40] Twelve weeks of once-weekly isoniazid and rifapentine by DOT was compared with daily self-administered isoniazid for 9 months in over 8,000 participants.[41] The isoniazid and rifapentine regimen was not inferior in efficacy to self-administered isoniazid, had a significantly higher completion rate (82% vs. 69%), and was associated with fewer grade 3 or 4 adverse reactions (1.6% vs. 3%).[41,42] Hypersensitivity reactions were more common with the isoniazid/rifapentine regimen and close clinical follow-up should be undertaken. These regimens are effective and safe.[42] The disadvantages of rifamycin-based regimens are the drug interactions. Rifabutin has less pronounced interactions than rifampin and may be used in place of rifampin due to contraindications or drug interactions. HIV-infected patients who are otherwise healthy and are not taking antiretroviral medications are also included in this category. The 3-month rifapentine and isoniazid combination is recommended for HIV-positive persons providing drug interactions allow.[40] Drug interactions with rifapentine vary with the frequency of the dose and the affected companion drug. Precautions should be taken as HIV-infected patients are more likely to have extrapulmonary TB or pulmonary TB with normal findings on chest radiograph.

Alternative options for treatment of LTBI include 6 or 9 months of isoniazid which carry a higher toxicity risk and lower treatment completion rates due to the longer length of therapy.[40] For recent skin-test converters of all ages, the risk of active TB outweighs the risk for drug toxicity.[40] Pregnant females, persons who misuse alcohol, and those with poor diets who are treated with isoniazid should receive pyridoxine (vitamin B6) 10 to 50 mg daily to reduce the incidence of central nervous system (CNS) effects or peripheral neuropathies. All patients who receive treatment of LTBI should be monitored monthly for adverse drug reactions and for possible progression to active TB. Newer regimens under investigation include 1 month of daily rifapentine plus isoniazid (tested in HIV-positive patients to date), and 6 weeks of rifapentine daily alone. When resistance to isoniazid and rifampin is suspected in the isolate causing infection, there are no randomized controlled trials to prove what regimen should be used to treat LTBI among contacts.[40]

Treating Active Disease

⑧ The treatment of active TB requires the use of multiple drugs. There are two primary antituberculosis drugs, isoniazid and rifampin.[36,38] Isoniazid and rifampin should be used together whenever possible. Typically, *M. tuberculosis* is either susceptible or resistant to a given drug. Theoretically, minimal inhibitory concentration results could be used to guide dosing in the treatment of moderately resistant *M. tuberculosis*, but this remains to be studied prospectively.[36,38]

Drug-susceptibility testing should be done on the initial isolate for all patients with active TB. These data should guide the selection of drugs over the course of treatment.[35,43] However, some patients are unable to provide a suitable specimen for laboratory testing. If susceptibility data are not available for a given patient, the drug susceptibility data for the suspected source case or regional susceptibility data should be used.[35,43]

Drug resistance should be expected for patients presenting for the retreatment of TB. These patients require retesting of drug susceptibility using freshly collected specimens. It is imperative to learn what drugs the patient received and for how long the patient received them.[35] A treatment history, often called a *drug-o-gram*, shows the start and stop dates of all antimycobacterial drugs on a horizontal bar graph.[35] A drug-o-gram should be constructed for all retreatment patients.

⑨ The standard TB treatment regimen is isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months, followed by isoniazid and rifampin for 4 months, a total of 6 months of treatment.[35] If susceptibility to isoniazid, rifampin, and pyrazinamide is shown, ethambutol can be stopped. Without pyrazinamide, a total of 9 months of isoniazid and rifampin treatment is required. Table 135-3 shows the recommended treatment regimens for drug susceptible tuberculosis. When intermittent therapy is used, DOT is essential. Doses missed during an intermittent TB regimen decrease its efficacy and increase the relapse rate. HIV-positive patients should not receive highly intermittent regimens. In general, regimens given daily five times each week or three times weekly can be used for HIV-positive patients. Less frequent dosing is associated with higher failure and relapse rates and the selection of rifampin-resistant organisms.[35]

TABLE 135-3

Drug Regimens for Microbiologically Confirmed Pulmonary Tuberculosis Caused by Drug Susceptible Organisms

Initial Phase			Continuation Phase		
Regimen	Drugs	Interval and Doses[a]	Drugs	Interval and Doses[a]	Comments[b,c]
1	Isoniazid Rifampin Pyrazinamide Ethambutol	Daily for 8 weeks 7 days/week for 56 doses or 5 days/week for 40 doses[d]	Isoniazid/Rifampin	7 days/week for 126 doses or 5 days/week for 90 doses	This is preferred regimen for patient with newly diagnosed pulmonary tuberculosis.
2	Isoniazid Rifampin Pyrazinamide Ethambutol	Daily for 8 weeks 7 days/week for 56 doses or 5 days/week for 40 doses[d]	Isoniazid/Rifampin	Three times weekly for 54 doses	Preferred alternative regimen in situations in which more frequent DOT during continuation phase is difficult to achieve.
3	Isoniazid Rifampin Pyrazinamide Ethambutol	Three times weekly for 8 weeks Three times weekly for 24 doses	Isoniazid/Rifampin	Three times weekly for 54 doses	Caution in patients with HIV and/or cavitary disease. Missed doses can lead to treatment failure, relapse, and acquired drug resistance.
4	Isoniazid Rifampin Ethambutol Pyrazinamide	Daily for 2 weeks, then twice weekly for 6 weeks 7 days/week for 14 doses, then twice weekly for 12 doses[e]	Isoniazid/Rifampin	Twice weekly for 36 doses	Do not use twice weekly regimens in HIV-infected patients or patients with smear positive and//or cavitary disease. If doses are missed, then therapy is equivalent to once weekly, which is inferior.

RIF, rifampin.

[a] When DOT is used, drugs may be given 5 days/week and the necessary number of doses adjusted accordingly. Although there are no studies that compare 5 with 7 daily doses, extensive experience indicates this would be an effective practice. DOT should be used when drugs are administered <7 days/week.

[b] Based on expert opinion, patients with cavitation on initial chest radiograph and positive cultures at completion of 2 months of therapy should receive a 7-month (31-week) continuation phase.

[c] Pyridoxine (vitamin B6), 25 to 50 mg/day, is given with isoniazid to all persons at risk of neuropathy (eg, pregnant women; breastfeeding infants; persons with HIV; patients with diabetes, alcoholism, malnutrition, or chronic renal failure; or patients with advanced age). For patients with peripheral neuropathy, experts recommend increasing pyridoxine dose to 100 mg/day.

[d] Five-day-a-week administration is always given by DOT.

[e] Alternatively, some US tuberculosis control programs have administered intensive-phase regimens 5 days/week for 15 doses (3 weeks), then twice weekly for 12 dose.

Executive Summary: Official American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America Clinical Practice Guidelines: Treatment of drug-susceptible tuberculosis. Clin Infect Dis. 1 October 2016;63(7):853–867.

When a patient's sputum smears convert to a negative, the risk of the patient infecting others is greatly reduced, but it is not zero.[35,44] Such patients can be removed from respiratory isolation, but they must be careful not to cough on others and should meet with others only in well-ventilated places. Smear-negative patients still may be culture positive, so they still can transmit TB to others.

Patients who are slow to respond clinically, those who remain culture-positive at 2 months of treatment, those with cavitary lesions on chest radiograph, and perhaps HIV-positive patients should be treated for a total of 9 months and for at least 6 months from the time that they convert to smear and culture negativity.[35,44] Some authors recommend therapeutic drug monitoring (TDM), the use of serum drug concentrations, to optimize therapy for such patients.[39,45,46] When isoniazid and rifampin cannot be used, treatment durations often become 2 years or more regardless of immune status.[35,44] The most promising shorter regimens for MDR-TB may be the combination of bedaquiline, pretomanid and linezolid, generally for 6 months.[47] The treatment of MDR-TB will continue to evolve.

⑩ Adjustments to the regimen should be made once the susceptibility data are available.[35] If the organism is drug-resistant, careful consideration of the remaining therapeutic options must be made. Two or more drugs with in vitro activity against the patient's isolate and that the patient has not received previously should be added to the regimen, as needed.[35,43] In the United States, there is no standard regimen for MDR-TB.[35,43,47] Each patient's exposure history, treatment history (including toxicity and adherence issues), and current susceptibility data must be considered simultaneously. *It is critical to avoid monotherapy, and it is critical to never add a single drug to a failing regimen.*[38,39] Adding one drug at a time leads to the sequential selection of drug resistance until there are no drugs left. TB specialists should be consulted regarding cases of MDR-TB. It may take several months for a patient with MDR-TB to become culture-negative because the drugs used lack the potency of isoniazid and rifampin.[35,46] Consequently, prolonged respiratory isolation may be required.

Drug resistance should be considered in the following situations:

1. Patients who have received prior therapy for TB.
2. Patients from areas with a high prevalence of resistance (South Africa, Dominican Republic, Peru, Southeast Asia, the Baltic countries, and the former Soviet states).
3. Patients who are homeless, institutionalized, use IV drug, or who are infected with HIV.
4. Patients who still have AFB-positive sputum smears after 1 to 2 months of therapy.
5. Patients who still have positive cultures after 2 to 4 months of therapy.
6. Patients who fail treatment or relapse after treatment.
7. Patients known to be exposed to MDR-TB cases.

Empirical therapy with four or more drugs may be needed for acutely ill patients.[35] These regimens may be altered when the susceptibility pattern becomes known. If the index case is known, then the same effective regimen should be employed for the new case, with help from specialists. *XDR-TB* refers to "extensively drug-resistant TB." Such organisms are resistant to at least isoniazid, rifampin, a fluoroquinolone, and either bedaquiline or linezolid; refer such cases to specialists.[48,49]

Special Populations

Tuberculous Meningitis and Extrapulmonary Disease

Patients with CNS TB usually are treated for longer periods (9-12 months instead of 6 months).[35] In general, isoniazid, pyrazinamide, ethionamide, cycloserine, and linezolid penetrate the cerebrospinal fluid readily, but rifampin, ethambutol, and amikacin have variable CNS penetration.[39] Of the quinolones, levofloxacin may be preferred. Extrapulmonary TB of the soft tissues can be treated with conventional regimens.[35] TB of the bone typically is treated for 9 months, occasionally with surgical debridement.[35]

Children

TB in children may be treated with regimens similar to those used in adults, although some physicians still prefer to extend treatment to 9 months.[35] Pediatric doses of isoniazid and rifampin on a milligram-per-kilogram basis are higher than those used in adults (Table 135-4).[35]

TABLE 135-4

Suggested Starting Doses[a] of First-Line Antituberculosis Drugs for Adults and Children[b,c]

Drug	Preparation	Adults/Children	Typical Doses			
			Daily	1× Per Week	2× Per Week	3× Per Week
First-Line Drugs						
Isoniazid	Tablets (50, 100, 300 mg); elixir (50 mg/5 mL); aqueous solution (100 mg/mL) for IV or intramuscular injection	Adults[c]	5 mg/kg	15 mg/kg	15 mg/kg	15 mg/kg
		Children[c]	10-15 mg/kg	—	20-30 mg/kg	—
Rifampin	Capsule (150, 300 mg); powder may be suspended for oral administration; aqueous solution for IV injection	Adults[d,e]	10 mg/kg	—	10 mg/kg	10 mg/kg
		Children[c]	10-20 mg/kg	—	10-20 mg/kg	—
Rifabutin	Capsule (150 mg)	Adult[d,e]	5 mg/kg	—	5 mg/kg	5 mg/kg
		Children	Appropriate dosing for children is unknown	Appropriate dosing for children is unknown	Appropriate dosing for children is unknown	Appropriate dosing for children is unknown
Rifapentine	Tablet (150 mg, film coated)	Adults[c]	20 mg per kg daily is now being used for active TB	15 mg/kg (900 mg) now is used for LTBI	—	—
		Children	The drug is not approved for use in children	The drug is not approved for use in children	The drug is not approved for use in children	The drug is not approved for use in children
Pyrazinamide	Tablet (500 mg, scored)	Adults[c]	Weight 40-55 kg: 1,000 mg	—	Weight 40-55 kg: 2,000 mg	Weight 40-55 kg: 1,500 mg
			Weight 56-75 kg: 1,500 mg	—	Weight 56-75 kg: 3,000 mg	Weight 56-75 kg: 2,500 mg
			Weight 76-90 kg: 2,000 mg	—	Weight 76-90 kg: 4,000 mg	Weight 76-90 kg: 3,000 mg

		Children[c]	15-30 mg/kg	—	50 mg/kg	—
Ethambutol	Tablet (100, 400 mg)	Adults[c]	Weight 40-55 kg: 800 mg	—	Weight 40-55 kg: 2,000 mg	Weight 40-55 kg: 1,200 mg
			Weight 56-75 kg: 1,200 mg	—	Weight 56-75 kg: 2,800 mg	Weight 56-75 kg: 2,000 mg
			Weight 76-90 kg: 1,600 mg	—	Weight 76-90 kg: 4,000 mg	Weight 76-90 kg: 2,400 mg
		Children[d,e]	15-20 mg/kg daily	—	50 mg/kg	—

Higher doses of rifampin and rifapentine are being studied. Rifabutin dose may need to be adjusted when there is concomitant use of protease inhibitors or non-nucleoside reverse transcriptase inhibitors.

[a] Dose per weight is based on ideal body weight. Children weighing more than 40 kg should be dosed as adults.

[b] For purposes of this document, adult dosing begins at age 15 years.

[c] The authors of this chapter do not agree with the use of maximum doses, since this arbitrarily caps doses for patients who otherwise might need larger doses. These maximum doses were not based on prospective studies in large or overweight individuals, and do not consider patients with documented malabsorption of their medications. Clinical judgment should be used in such circumstances.

[d] The drug can likely be used safely in older children but should be used with caution in children younger than 5 years, in whom visual acuity cannot be monitored. In younger children, ethambutol at the dose of 15 mg/kg/day can be used if there is suspected or proven resistance to isoniazid or rifampin.

[e] It should be noted that, although this is the dose recommended generally, most clinicians with experience using cycloserine indicate that it is unusual for patients to be able to tolerate this amount. Serum concentration measurements are often useful in determining the optimal dose for a given patient.

Data from Reference 36.

Pregnancy

Females with TB should be cautioned against becoming pregnant because the disease poses a risk to the fetus and to the mother. If already pregnant, the usual treatment is isoniazid, rifampin, and ethambutol for 9 months.[50] Isoniazid and ethambutol are relatively safe for use in pregnant females.[50] B vitamins are particularly important during pregnancy and should be provided to females being treated for TB. Rifampin is associated rarely with birth defects, including limb reduction and CNS lesions.[35,50] In general, rifampin is used in pregnant females with TB. Pyrazinamide has not been studied in large numbers of pregnant women, but anecdotal data suggest that it may be safe.[35]

Aminoglycoside use during pregnancy may lead to hearing loss in the newborn, including complete deafness. Aminoglycosides must be reserved for critical situations where alternatives do not exist.[35] Although the polypeptide capreomycin has not been studied, it probably carries the same risks.

Ethionamide may cause premature delivery and congenital deformities when used during pregnancy.[35,50] Down syndrome also has been reported with ethionamide, so it cannot be recommended in this setting. *p*-Aminosalicylic acid has been used safely in pregnancy, but specific data are lacking.[50] Cycloserine is known to cross the placenta, but the effects on the developing fetus are not known. Therefore, cycloserine generally cannot be recommended during pregnancy.[50]

Ciprofloxacin, levofloxacin, moxifloxacin, and the other quinolones are associated with permanent damage to cartilage in the weight-bearing joints of immature animals, especially dogs and rabbits.[50] Although these drugs do not frequently cause joint problems in humans, other antituberculosis agents should be used during pregnancy.

Pregnant females with LTBI are not at the same level of risk compared with those with active disease. Therapy for LTBI may be delayed until after pregnancy. However in the case of recent infection documented by a skin-test conversion or a newly positive IGRA and in immunosuppressed females who are found to have LTBI while pregnant, treatment for LTBI is started during the second trimester of pregnancy.[40,50] Although most antituberculosis drugs are excreted in breast milk, the amount of drug received by the infant through nursing is insufficient to cause toxicity. Quinolones should be avoided in nursing mothers.[51]

HIV Infection

For drug-susceptible strains of tuberculosis, patients with AIDS and other immunocompromised hosts may be managed with chemotherapeutic regimens similar to those used in immunocompetent individuals, although treatment is often extended to 9 months (see Table 135-3).[23,35] The precise duration to recommend remains a matter of debate. Highly intermittent regimens (twice or once weekly) are not recommended for HIV-positive TB patients. Rifamycin-based treatments are most effective; however, agents should be selected based on susceptibility and HIV drug interactions. Prognosis has been particularly poor for HIV-infected patients infected with MDR-TB, so all efforts should be made to reduce the time between clinical presentation, diagnosis of TB, and start of appropriate treatment. Recommendations for management of HIV and TB published by the World Health Organization (WHO) and others have provided guidance on monitoring of treatment, side effects, and drug interactions of HIV and TB, MDR, and XDR-TB.[23,52] The timing for antiretroviral treatment in patients with TB and HIV is unclear. In patients with CD4 cell counts $<200/\text{mm}^3$ (0.20×10^9/L) or $<50/\text{mm}^3$ (0.05×10^9/L) reductions in mortality have been seen when antiretroviral treatment was initiated within 2 weeks of antituberculosis treatment.[52,53] Differentiation must be made between infection with *M. tuberculosis* and nontuberculous mycobacteria, such as *M. avium* complex, because the drugs used are different. While awaiting laboratory results, the patient can be treated empirically for TB if there is any doubt about the causative organism. Some patients with AIDS malabsorb their oral medications; this is discussed in the “Therapeutic Drug Monitoring” section below.[45]

Renal Failure

For nearly all patients, isoniazid and rifampin do not require dose modification in renal failure. They are eliminated primarily by the liver.[39] In the unlikely event that peripheral neuropathies develop, the frequency of isoniazid dosing may be reduced. Pyrazinamide and ethambutol typically require a reduction in dosing frequency from daily to three times weekly (Table 135-5).[35,39]

TABLE 135-5

Dosing Recommendations for Adult Patients with Reduced Renal Function and for Adult Patients Receiving Hemodialysis

Drug	Change in Frequency?	Recommended Dose and Frequency for Patients with Creatinine Clearance <30 mL/min (0.50 mL/s)[a,b,c,d]
Isoniazid	No change	300 mg once daily or 900 mg three times per week
Rifampin	No change	600 mg once daily or 600 mg three times per week
Pyrazinamide	Yes	25-35 mg/kg per dose three times per week (not daily)
Ethambutol	Yes	15-25 mg/kg per dose three times per week (not daily)
Levofloxacin	Yes	750-1,000 mg per dose three times per week (not daily)
Cycloserine	Yes	250 mg once daily, or 500 mg/dose three times per week[e]
Ethionamide	No change	250-500 mg/dose daily
p-Aminosalicylic acid	No change	4 g/dose, twice daily
Streptomycin	Yes	12-15 mg/kg per dose two or three times per week (not daily)
Capreomycin	Yes	12-15 mg/kg per dose two or three times per week (not daily)
Kanamycin	Yes	12-15 mg/kg per dose two or three times per week (not daily)
Amikacin	Yes	12-15 mg/kg per dose two or three times per week (not daily)

[a] Standard doses are given unless there is intolerance.

[b] The medications should be given after hemodialysis on the day of hemodialysis.

[c] Monitoring of serum drug concentrations should be considered to ensure adequate drug absorption, without excessive accumulation, and to assist in avoiding toxicity.

[d] Data are not available for patients receiving peritoneal dialysis. Until data become available, begin with doses recommended for patients receiving hemodialysis and verify adequacy of dosing, using serum concentration monitoring.

[e] The appropriateness of 250-mg daily doses has not been established. There should be careful monitoring for evidence of neurotoxicity.

Reprinted, with permission, from Nahid P, et al. Executive Summary: Official American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America Clinical Practice Guidelines: Treatment of drug-susceptible tuberculosis. Clin Infect Dis. 1 October 2016;63(7):853–867.

Renally cleared TB drugs include the aminoglycosides (amikacin, kanamycin, and streptomycin), capreomycin, ethambutol, cycloserine, and levofloxacin.[35,39,54] Dosing intervals need to be extended for these drugs (Table 135-5). Moxifloxacin is approximately 50% cleared by the kidneys but may not require a change in dose from once daily, as used for TB. The metabolites of isoniazid, pyrazinamide, and *p*-aminosalicylic acid are cleared primarily by the kidneys. The role of these metabolites in causing toxicity is unknown, so their accumulation in renal failure may carry some risk.

Ethionamide and its sulfoxide metabolite are hepatically cleared, so dosing is unchanged.[35,54] *p*-Aminosalicylic acid is converted largely to metabolites prior to renal elimination; these metabolites may accumulate in renal failure.[54,55] For patients on hemodialysis, the usual 12-hour dosing interval for *p*-aminosalicylic acid granules seems to be safe. Dialysis will remove the metabolites. Serum concentration monitoring must be performed for cycloserine to avoid dose-related toxicities in renal failure patients.[55] Data regarding peritoneal dialysis are lacking. Ethambutol should be avoided in peritoneal dialysis patients, based on anecdotal evidence.

Hepatic Failure

Antituberculosis drugs that rely on hepatic clearance for most of their elimination include isoniazid, rifampin, pyrazinamide, ethionamide, and *p*-aminosalicylic acid.[39] Moxifloxacin is approximately 50% cleared by the liver. Elevations of serum transaminase concentrations generally are not correlated with the residual capacity of the liver to metabolize drugs, so these markers cannot be used as guides for drug dosing. Furthermore, isoniazid, rifampin, pyrazinamide, and, to a lesser degree, ethionamide, *p*-aminosalicylic acid, and, rarely, ethambutol may cause hepatotoxicity.[35,38,39] For some patients with drug-susceptible TB, a "liver-sparing" regimen may include linezolid, amikacin, levofloxacin, or ethambutol, at least temporarily.[35,38,39] Because this regimen requires 18 or more months of treatment to be successful, patients usually are switched to isoniazid- and rifampin-containing regimens as soon as they are able.

Morbid Obesity

Data are not available for dosing the TB drugs for patients with morbid obesity.[39] Relatively hydrophilic drugs (isoniazid, pyrazinamide, the aminoglycosides, capreomycin, *p*-aminosalicylic acid, and cycloserine) can be dosed initially based on ideal body weight. Low or high serum concentrations can be avoided by checking the serum concentrations.[45]

The TB Drugs

The interested reader is referred to several other publications for more detailed information regarding these drugs (see Table 135-4).[35,44,45] The "maximum" dose for a given patient is the dose that produces the desired response with an acceptable level of toxicity.[45] This can only be determined on a case-by-case basis. Artificially capping doses may deprive patients of needed drug.

Primary Antituberculosis Drugs

Isoniazid

Isoniazid is one of the two most important TB drugs. It is highly specific for mycobacteria, with a minimal inhibitory concentration against *M. tuberculosis* of 0.01 to 0.25 mcg/mL (mg/L; 0.07-1.82 μmol/L). It is bactericidal and is thought to inhibit mycolic acid synthesis and disruption of the cell wall in susceptible organisms.[56] Most nontuberculous mycobacteria such as *M. avium* are resistant to isoniazid, although *M. kansasii* and *M. xenopi* are susceptible. The most common mechanisms of resistance result from mutations in the *katG* or *inhA* genes.[56]

Isoniazid is readily absorbed from the GI tract and from intramuscular injection sites. It also can be given as a short IV infusion over 5 minutes if diluted in about 20 mL of normal saline.[57] Isoniazid should be given on an empty stomach whenever possible.[57] *N*-Acetyltransferase 2 forms the principal metabolite acetylisoniazid, which lacks antimycobacterial activity. The rate at which humans acetylate isoniazid is determined genetically; slow acetylation is an autosomal recessive trait and reflects a relative lack of *N*-acetyltransferase 2. Fast acetylators have isoniazid half-lives of less than 2 hours. Approximately 50% of Whites and Blacks and 80% to 90% of Asians and Native Alaskans are rapid acetylators. Slow acetylators have isoniazid half-lives of 3 to 4 hours and may be at an increased risk of neurotoxicity. The association of acetylator status and risk of hepatotoxicity, however, appears to be weak.[56] Poor absorption and rapid clearance of isoniazid for patients receiving highly intermittent therapy are associated with poor clinical outcomes.[56,58]

Transient elevations of the serum transaminases occur in 12% to 15% of patients receiving isoniazid and usually occur within the first 8 to 12 weeks of therapy.[35] Overt hepatotoxicity, however, occurs in only 1% of cases. Risk factors for hepatotoxicity include patient age, preexisting liver disease, excessive alcohol intake, pregnancy, coadministration of other medications that are potentially hepatotoxic, and the postpartum state. Isoniazid also may result in neurotoxicity, most frequently presenting as peripheral neuropathy or, in overdose, as seizures and coma. Patients with pyridoxine deficiency, such as pregnant females, persons who misuse alcohol, children, and the malnourished, are at increased risk. Isoniazid may inhibit the metabolism of phenytoin, carbamazepine, primidone, and warfarin.[38] Patients who are being treated with these agents should be monitored closely, and appropriate dose adjustments should be made when necessary.

Rifampin

The introduction of rifampin into routine use during the 1970s allowed for true short-course treatment of TB (6-9 months).[35] Without rifampin, treatment is generally 18 months or longer. Drug resistance to rifampin is an ominous prognostic factor because it is frequently associated with isoniazid resistance and leaves the patient with few good therapeutic options. Clinicians *must* take care to protect susceptibility to rifampin by carefully treating their patients. Rifampin shows bactericidal activity against *M. tuberculosis* and several other mycobacterial species, including *M. bovis* and *M. kansasii*.[59] It is also active against a broad array of other bacteria. Alteration of the target site on RNA polymerase, primarily through changes in the *rpoB* gene, leads to most forms of rifampin resistance.[35,59]

Rifampin usually is given orally, but it also can be given as a 30-minute IV infusion.[59] Oral doses are best given on an empty stomach.[60] Patients with AIDS, diabetes, and other GI problems have difficulty absorbing rifampin after oral doses, and this has been associated with therapeutic failures in some cases.[35,59,61] Rifampin is metabolized to 25-desacetyl rifampin, which retains some of rifampin's activity; most of rifampin and its metabolite are cleared in the bile. Rifampin generally is given at 600 mg daily or intermittently, although this dose does not take full advantage of rifampin's concentration-dependent killing.[39,45] Higher doses (1,200-2,400 mg) are being considered based on clinical trials.[62]

Elevations in hepatic enzymes have been attributed to rifampin in 10% to 15% of patients, with overt hepatotoxicity occurring in less than 1%.[35,59] More frequent adverse effects of rifampin include rash, fever, and GI distress. Allergic reactions to rifampin have been reported and occur more frequently with intermittent rifampin doses 900 mg or more twice weekly. These reactions may take the form of a flu-like syndrome with development of fever, chills, headache, arthralgias, and, rarely, hypotension and shock.[36] Alternatively, hemolytic anemia or acute renal failure may occur, requiring permanent discontinuation.

Rifampin's potent induction of hepatic enzymes, especially cytochrome P450 3A4, may enhance the elimination of many other drugs, most notably the protease inhibitors used to treat HIV (Table 135-6). HIV-positive patients may benefit from the use of rifabutin instead of rifampin.[23,35,60] Furthermore, women who use oral contraceptives must use another form of contraception during therapy because increased clearance of the hormones may lead to unexpected pregnancies. Patient records should be reviewed for potential drug interactions before dispensing rifampin. Rifampin may turn urine and other secretions orange-red and may permanently stain some types of contact lenses.

TABLE 135-6

Recommended Regimens for the Concomitant Treatment of TB and HIV Infection in Adults

Combined Regimen for Treatment of HIV and TB	Pharmacokinetic Effect of the Rifamycin	Tolerability/Toxicity	Antiviral Activity When Used with Rifamycin	Recommendations (Comments)
Efavirenz-based antiretroviral therapy[a] with rifampin-based TB treatment	Well-characterized, modest decrease in concentrations in some patients	Low rates of discontinuation	Excellent	Preferred (efavirenz should not be used during the first trimester of pregnancy)
PI-based antiretroviral therapy[a] with rifabutin-based TB treatment	Little effect of rifabutin on PI concentrations, but marked increases in rifabutin	Low rates of discontinuation (if rifabutin is appropriately dose-reduced)	Favorable, although published clinical experience is not extensive	Preferred for patients unable to take efavirenz[b] (caution to ensure patients who discontinue PI not to continue to receive reduced rifabutin dose)

	concentrations			
Nevirapine-based antiretroviral therapy with rifampin-based TB treatment	Moderate decrease in concentrations	Concern about hepatotoxicity when used with isoniazid, rifampin, and pyrazinamide	Suboptimal when nevirapine is initiated using once-daily dosing largely favorable when nevirapine is given twice daily throughout cotreatment	Alternative for patients who cannot take efavirenz, though efavirenz is preferred (nevirapine should not be initiated among women with CD4 > 250 cells/μL [0.25 × 10^9/L] or men with CD4 > 400 cells/μL [0.40 ×10^9/L])
Raltegravir-based antiretroviral therapy with rifampin-based TB treatment	Significant decrease in concentrations with standard dosing	Limited experience	Limited published clinical experience	Alternative at higher doses for patients who cannot take efavirenz and who have baseline viral load <100,000 copies/mL (100 × 10^6/L)
Dolutegravir-based antiretroviral therapy with rifampin-based TB-treatment	Coadministration with rifampicin results in decreases in dolutegravir plasma exposure requiring increased dose of dolutegravir	Limited experience	Limited published clinical experience	Alternative for patients who cannot take efavirenz
Zidovudine/lamivudine/abacavir/tenofovir with rifampin-based TB treatment	50% decrease in zidovudine, possible effect on abacavir not evaluated	Anemia	No published clinical experience, but this regimen is less effective than efavirenz or atazanavir based-regimens in person not taking rifampin	Alternative for patients who cannot take efavirenz or nevirapine and if rifabutin not available
Zidovudine/lamivudine/tenofovir with rifampin-based TB treatment	50% decrease in zidovudine, no other effects predicted	Anemia	Favorable, but not evaluated in a randomized trial	Alternative for patients who cannot take efavirenz and abacavir and if rifabutin not available
Zidovudine/lamivudine/abacavir with rifampin-based TB treatment	50% decrease in zidovudine, possible effect on abacavir not evaluated	Anemia	Early favorable experience, but this combination is less effective than efavirenz- or nevirapine-based regimens in persons not taking rifampin	Alternative for patients who cannot take efavirenz and tenofovir and if rifabutin not available

Superboosted[c] lopinavir-based antiretroviral therapy or double dose lopinavir/ritonavir-based therapy with rifampin-based TB treatment	Moderate decrease in concentrations	Hepatitis	Early favorable experience of super-boosting among young children and double dose among adults already on antiretroviral drugs at the time of rifampin initiation	Alternative if rifabutin not available; double dose an option among adults already taking lopinavir-based antiretroviral therapy and virologically suppressed at the time of tuberculosis treatment initiation; super boosting has not been adequately tested in adults but may be effective

[a] With two nucleoside analogues.

[b] Includes patients with NNRTI-resistant HIV, those unable to tolerate efavirenz, and women during the first one to two trimesters of pregnancy.

[c] Super boosting of lopinavir is achieved by giving lopinavir 400 mg together with 400 mg ritonavir twice daily. Double dose lopinavir/ritonavir is lopinavir 800 mg plus ritonavir 200 mg twice daily.

Data from Managing Drug Interactions in the Treatment of HIV-Related Tuberculosis. 2013. Available at: https://www.cdc.gov/tb/publications/guidelines/tb_hiv_drugs/recommendations02.htm

Other Rifamycins

Rifabutin is used for disseminated *M. avium* infection in AIDS patients and is quite active against *M. tuberculosis*. Most rifampin-resistant organisms are resistant to rifabutin. Because rifabutin is a less potent enzyme inducer than rifampin, it may be used for patients who are receiving HIV protease inhibitors.[36,50,61,62] For HIV-positive patients, the American Thoracic Society/CDC recommends regimens with three or more doses of the TB drugs per week (see Table 135-3). Rifapentine is a long-acting rifamycin that has been tested as part of a 4-month regimen that includes moxifloxacin for selected TB patients.[63] It is approximately as potent an enzyme inducer as rifampin, so similar drug interactions are likely.[52,64]

Pyrazinamide

Adding pyrazinamide to the first 2 months of treatment with isoniazid and rifampin shortens the duration to 6 months for most patients.[35] Pyrazinamide may be bacteriostatic or bactericidal depending on the concentration and the susceptibility of the organism. It is usually well absorbed and displays a fairly long half-life.[39,65] The most common toxicities of pyrazinamide are GI distress, arthralgias, and elevations in the serum uric acid concentrations.[35,44] Most patients do not experience true gout. Hepatotoxicity is the major limiting adverse effect and is dose-related when pyrazinamide is given daily.

A fixed-combination product (rifater) of rifampin 120 mg, isoniazid 50 mg, and pyrazinamide 300 mg is designed to prevent drug resistance by keeping the self-medicating patient from using only one drug at a time. If the patient is receiving DOT, there is no particular advantage to this product. The typical dose of rifater will be five to six tablets daily. When pyrazinamide is discontinued after 2 months of treatment, the combination product rifamate (isoniazid 150 mg and rifampin 300 mg) can be substituted.

Ethambutol

Ethambutol replaced *p*-aminosalicylic acid as a first-line agent in the 1960s because it was better tolerated by patients.[39] It is used as a fourth drug for TB while awaiting susceptibility data and its use is intended to prevent emergence of rifampin resistance.[35,44] If the organism is susceptible to isoniazid, rifampin, and pyrazinamide, ethambutol can be stopped. Ethambutol is active against most mycobacteria, by inhibiting synthesis of metabolites and impairing cell metabolism, and is generally bacteriostatic.

Ethambutol should not be given with antacids.[66,67] For patients with renal failure, the ethambutol dose should be reduced to three times per week.[68] Retrobulbar neuritis is the major adverse effect. Patients may complain of a change in visual acuity, the inability to see the color green, or both. They should be monitored monthly while on the drug using Snellen wall charts for visual acuity and Ishihara red-green color discrimination cards.[35]

Quinolones

Levofloxacin and moxifloxacin are sometimes used to treat MDR-TB because of their excellent activity against *M. tuberculosis*. Table 135-7 lists WHO proposed categories of drugs for treating MDR-TB and XDR-TB. Moxifloxacin is a possible replacement for certain first-line agents.[69,70] Moxifloxacin has been compared with isoniazid and ethambutol during the first 8 weeks of therapy for pulmonary TB. There was no significant increase in 8-week culture negativity when compared with isoniazid. However, shorter time to culture conversion was seen when compared with ethambutol.[70] Quinolones are useful because most are available in oral and IV dosage forms, so they can be used in critically ill patients. However, resistance of MTB to the fluoroquinolones is a major concern. Resistance is attributed to mutations in the gyrA and gyrB genes and can develop in a relatively short period of time.[59,71]

TABLE 135-7

The WHO Proposed Categories of Drugs for Treating MDR- and XDR-TB[a]

Groups and steps	Medicine
Group A: Include all three medicines	Levofloxacin or moxifloxacin
	Bedaquiline[b,c]
	Linezolid[d]
Group B: Add one or both medicines	Clofazimine
	Cycloserine or terizidone
	Ethambutol
	Delamanid[d]
	Pyrazinamide[f]
Group C: Add to complete the regimen and when medicines from Groups A and B cannot be used	Imipenem–cilastatin or meropenem[g]
	Amikacin (or streptomycin)[h]
	Ethionamide orprothionamide[i]
	P-aminosalicylic acidi

ECG: electrocardiogram; GDG: Guideline Development Group; IPD: individual patient data; LPA: line probe assay.

[a]This table is intended to guide the design of individualized, longer MDR-TB regimens medicines in Group C are ranked by decreasing order of usual preference for use, subject to other considerations.

[b] *Adapted from Nahid P, et al. Executive Summary: Official American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America Clinical Practice Guidelines: Treatment of drug-susceptible tuberculosis. Clin Infect Dis. 1 October 2016;63(7):853–867.*

[c] In 2019, new evidence on the concurrent use of bedaquiline and delamanid was made available to the GDG. With regard to safety, the GDG concluded that the data suggest no additional safety concerns regarding concurrent use of bedaquiline and delamanid. Both medicines may be used concurrently in patients who have limited other treatment options available to them, provided that sufficient monitoring (including baseline and follow-up ECG and electrolyte monitoring) is in place. The data on the effectiveness of concurrent use of bedaquiline and delamanid were reviewed by the GDG, but owing to the limited evidence and potential residual confounding in the data, the GDG was unable to proceed with a recommendation on effectiveness.

[d] Use of linezolid for at least 6 months has been shown to increase effectiveness, although toxicity may limit use.

[e] Evidence on the safety and effectiveness of delamanid beyond 6 months and in children aged under 3 years was insufficient for review. The use of delamanid beyond these limits should follow best practices in “off-label” use.

[f] Pyrazinamide is counted as an effective agent only when confirmed susceptibility.

[g] Every dose of imipenem–cilastatin and meropenem is administered with clavulanic acid, which is available only in formulations combined with amoxicillin. Amoxicillin–clavulanic acid is not counted as an additional effective TB agent and should not be used without imipenem–cilastatin or meropenem.

[h] Amikacin and streptomycin are to be considered only when confirmed susceptibility, and if high-quality audiometry monitoring for hearing loss can be ensured. Streptomycin is to be considered only if amikacin cannot be used and confirmed susceptibility (ie, resistance to streptomycin is not detectable with second-line molecular LPAs and phenotypic drug-susceptibility testing is required). Kanamycin and capreomycin are no longer recommended for use in MDR-TB regimens.

[i] These agents showed effectiveness only in regimens without bedaquiline, linezolid, clofazimine or delamanid, and are thus proposed only when other options to compose a regimen are not possible.

Bedaquiline

Bedaquiline is a diarylquinoline that operates by a new mechanism which targets the ATP synthase pump and depletes cellular energy stores and does not demonstrate cross-resistance with existing TB drugs.[72,73] The WHO and CDC have issued recommendations stating that bedaquiline may be used at a dose of 400 mg daily for 2 weeks and then 200 mg three times a week for 22 weeks of treatment in adults with pulmonary MDR-TB when an effective treatment regimen cannot otherwise be provided.[74] Bedaquiline may be used on a case-by-case basis in children, HIV-infected persons, pregnant females, and in individuals with extrapulmonary TB. Patients treated with bedaquiline should be closely monitored every week for potential side effects and an electrocardiogram (QT monitoring) should be performed at baseline and at weeks 2, 12, and 24.[71,74] The QT monitoring is required due to a black box warning issued by the FDA as a result of increased rates of death due to QT prolongation in patients receiving bedaquiline.[72,73]

Linezolid

Linezolid, a synthetic inhibitor of ribosomal translation that has been used for drug-resistant Gram-positive infections since 2000.[71] It has oral bioavailability near 100% that is not affected by food.[71,75] Clearance involves oxidation of the morpholine ring, and renal elimination of parent drug plus metabolites.[59,71,75] CSF concentrations are 57% of plasma.[75] The most frequently used dose for TB is 600 mg once daily. Higher doses appear to be more toxic.[35,74,76] Trough concentrations are associated with mitochondrial toxicity, leading to cytopenias and peripheral and ocular neuropathies.[71] Rifampin can reduce linezolid plasma exposure by about a third.[71] Linezolid is a weak inhibitor of monoamine oxidase and should usually not be used with MAOIs, SSRIs or triptans due to reports of serotonergic syndrome.[75]

Clofazimine

Clofazimine is a drug with good activity against *M. leprae* and some activity against *M. tuberculosis* and *M. avium*. It is used in doses of 100 mg daily in advanced cases of MDR-TB or *M. avium* complex, especially when therapeutic options are limited.[35,39] The drug has a terminal elimination half-life that is weeks long. GI distress and skin discoloration are the most important adverse reactions. Although uncommon, severe GI pain may occur because of deposition of clofazimine crystals within the intestines; this may require surgical correction.[75]

Delamanid and Pretomanid

Delamanid and Pretomanid are nitroimidazole derivatives that are chemically related to metronidazole and work through inhibiting mycolic acid synthesis.[75,77] These agents have potent in vitro and in vivo activity with low minimal inhibitory concentrations against *M. tuberculosis*.[78] Delamanid has centralized marketing authorization by the European Medicines Agency for use in the European Union.[78] Pretomanid is FDA-approved as part of a regimen including bedaquiline and linezolid, the so-called BPaL regimen. Food increases pretomanid absorption.[73,79] Pretomanid is metabolized by multiple reductive and oxidative pathways, with CYP3A4 responsible for approximately 20%.[70] Efavirenz reduces the AUC of pretomanid by 35%, and rifampin reduces the AUC by 66%.[73,79] Combinations of pretomanid with other antituberculosis drugs are also being investigated.

Beta-lactams: Imipenem, Meropenem, and Ceftazidime

Imipenem and meropenem are synthetic carbapenems, and ceftazidime is a third generation cephalosporin.[59,75] These antibiotics target penicillin-binding proteins which are involved in bacterial cell-wall synthesis.[59,75] Resistance occurs by enzymatic degradation. Specifically, *M. tuberculosis* possesses an extended spectrum class A β-lactamase (BlaC), which must be inactivated.[75] Clavulanic acid and avibactam are beta-lactamase inhibitors that prevent the enzymatic degradation caused by β-lactamase.[59,75,80] Clavulanic acid can be given orally (only in combination with amoxicillin); the other drugs are given intravenously.[71] Dosing has been empiric, and has not been established. Imipenem has been dosed at 1,000 mg 12 hours and meropenem at 1000 mg 8 hours, intravenously.

Aminoglycosides

Streptomycin, amikacin, and kanamycin are active against mycobacteria, and amikacin is preferred for TB. Aminoglycosides are given IM or IV and are renally cleared by glomerular filtration. They must be dosed appropriately in patients with renal dysfunction.[45,79]

Aminoglycosides occasionally cause nephrotoxicity, although it tends to be mild and reversible. They also cause ototoxicity (vestibular and cochlear), which may become permanent with continued use.[59,79] Older patients and those receiving long durations of treatment are most likely to experience hearing loss, whereas vestibular toxicity is highly unpredictable.[59]

Ethionamide

Ethionamide shares structural features with two other antimycobacterial agents, isoniazid and thiacetazone, a drug not used in the United States. Prothionamide, the n-propyl derivative of ethionamide, is used in Europe. Ethionamide is only active against organisms of the genus *Mycobacterium*, and it should be considered primarily bacteriostatic because it is difficult to achieve serum concentrations that would be bactericidal.[39,59] GI toxicity is the dose-limiting adverse effect. The drug should be introduced gradually in 250-mg increments, as described earlier for cycloserine. Rarely will a patient tolerate more than 1,000 mg daily in divided oral doses. Ethionamide may be administered with a light snack or prior to bedtime to minimize GI intolerance. Food does not affect absorption significantly.[81] Little ethionamide is recovered in the urine, so doses remain the same in renal failure.[55] Ethionamide may cause goiter with or without hypothyroidism (especially when given with p-aminosalicylic acid), gynecomastia, alopecia, impotence, menorrhagia, and photodermatitis. The management of diabetes also may be more difficult for patients receiving ethionamide. Because of these problems, ethionamide only is used when necessary.

p-Aminosalicylic Acid

In the United States, only the enteric-coated, sustained-release granule form (Paser) is available.[39,82] GI disturbances are the most common adverse effects from *p*-aminosalicylic acid. Diarrhea is usually self-limited, with symptoms improving after the first 1 to 2 weeks of therapy. Occasionally, a few doses of an opioid will resolve the problem. It also is important to tell the patient that the empty granules will appear in the stool. Although FDA-approved for three daily doses, pharmacokinetic data support twice-daily dosing.[83,84]

Various types of malabsorption, including steatorrhea, were reported with previous dosage forms of *p*-aminosalicylic acid. Hypersensitivity and, rarely, severe hepatitis may occur. *p*-Aminosalicylic acid is known to produce goiter, with or without myxedema, which seems to occur more frequently with concomitant ethionamide therapy.[39,59]

Other New Drugs and Delivery Systems

Other new drugs in Phase II trials for treatment of TB include: Delpazolid (LCB01-0371) and sutezolid (PNU-100480) that target protein synthesis. SQ-109 is a new chemical class that targets MmpL3, an essential membrane transporter involved in the building of the mycolic acids as part of the outer membrane of mycobacteria. Macozinone (PBTZ-169) targets the flavoenzyme DprE1, blocking the synthesis of the cell wall precursor decaprenyl phosphoarabinose and provoking lysis of the *M. tuberculosis*. Liposomes are under investigation as delivery systems for various agents against mycobacteria, including isoniazid, rifampin, and the aminoglycosides. By changing the pharmacokinetic profile of such agents, their use in the treatment of mycobacterial infections could be enhanced greatly.

Corticosteroids

Adjunctive therapy with corticosteroids may be of benefit for some patients with tuberculous meningitis or pericarditis to relieve inflammation and pressure.[35] They should be avoided in most other circumstances because they detract from the immune response to TB.

Bacille Calmette-Guérin Vaccine

The BCG vaccine is an attenuated, hybridized strain of *M. bovis*. It was developed in 1921 and is used as a prophylactic vaccine against TB. Administration of BCG vaccine is compulsory in many developing countries and is officially recommended in many others. Vaccination with BCG produces a subclinical infection resulting in sensitization of T lymphocytes and cross-immunity to *M. tuberculosis*, as well as cutaneous hypersensitivity and, in many cases, a positive TST.

The efficacy of several different BCG preparations ranged from negative 56% (some patients did worse with the vaccine) to positive 80%.[36,85] The primary benefit of BCG vaccination appears to be the prevention of severe forms of TB in children.[86] The incidence of tuberculous meningitis and miliary TB is 52% to 100% lower and incidence of pulmonary TB is 2% to 80% lower in vaccinated children younger than 15 years than it was in unvaccinated controls.[86,87]

Side effects occur in 1% to 10% of vaccinated persons and usually include severe or prolonged ulceration at the vaccination site, lymphadenitis, and lupus vulgaris. Pregnant women and patients with impaired immune systems, including those with HIV infection, should avoid vaccination. The WHO had recommended, however, that in populations where the risk of TB is high, HIV-infected infants who are asymptomatic should receive BCG vaccine at birth or as soon as possible thereafter. Because BCG infection has occurred in AIDS patients given the vaccine, individuals with symptomatic HIV infection should not be vaccinated.[35]

THERAPEUTIC DRUG MONITORING

TDM, or applied pharmacokinetics, generally should be used if patients are failing appropriate treatment (no clinical improvement after 2-4 weeks or smear positive after 4-6 weeks).[45,79,88] Patients with AIDS, diabetes, obesity, cystic fibrosis, various GI disorders, or MDR-TB may be tested prospectively, before problems arise, to ensure adequate treatment. Blood samples collected at 2 and 6 hours after a dose have been used with some success, although they may not be the optimal sampling times for all the drugs.[89,90] Finally, TDM of the TB and HIV drugs is perhaps the most logical way to untangle the complex drug interactions that take place.[52,91]

EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring of the Pharmaceutical Care Plan

The most serious problem with TB therapy is patient nonadherence to the prescribed regimens.[35] Unfortunately, there is no reliable way to identify such patients a priori. Noncompliance rates of up to 89% have been reported with TB therapy.[89,92] It is critical to the control of TB that such adherence rates be improved dramatically. The most effective way to achieve this end is with DOT.[35] Despite criticisms that it will cost more money, DOT is far cheaper in the long run to prevent the further spread of disease with DOT than to track down and treat additional cases of TB continuously.

The homeless and other underprivileged individuals are often assumed to constitute a group of patients considered "unreliable," and DOT should be reserved for them; it is also assumed that "responsible" patients cared for by private physicians may be treated with daily, unsupervised therapy. However, outcomes (sputum culture conversion to negative at 3 months) for patients with pulmonary TB who were treated by private physicians were compared with outcomes for patients treated via DOT in a city-run clinic. Three-month culture conversion occurred in only 40% of the private-care patients, compared with 90% in the city clinic-care patients.[89,92] Clearly, expansion of the use of DOT to nearly all patients with TB may be of benefit.

Patients who are AFB-smear positive should have sputum samples sent for AFB stains every 1 to 2 weeks until two consecutive smears are negative. This provides early evidence of a response to treatment.[35] Once on maintenance therapy, sputum cultures can be performed monthly until two consecutive cultures are negative, which generally occurs over 2 to 3 months. If sputum cultures continue to be positive after 2 months, drug-susceptibility testing should be repeated, and serum concentrations of the drugs should be checked.

Serum chemistries, including blood urea nitrogen, creatinine, aspartate transaminase, and alanine transaminase, and a complete blood count with platelets should be performed at baseline and periodically thereafter, depending on the presence of other factors that may increase the likelihood of toxicity (eg, advanced age, alcohol abuse, pregnancy)[35] (Table 135-8). Hepatotoxicity should be suspected for patients whose serum transaminases exceed five times the upper limit of normal or whose total bilirubin concentration exceeds 3 mg/dL (51.3 µmol/L) and for patients with symptoms such as nausea, vomiting, or jaundice. At this point, the offending agent(s) should be discontinued. Sequential reintroduction of the drugs with frequent testing of liver enzymes is often successful in identifying the offending agent; other agents may be continued. Alternative agents should be selected as needed. Audiometric testing should be performed at baseline and monthly for patients who must receive aminoglycosides for more than 1 to 2 months. Vision testing (Snellen visual acuity charts and Ishihara color discrimination plates) should be performed on all patients who receive ethambutol. All patients diagnosed with TB should be tested for HIV infection.

TABLE 135-8

Antituberculosis Drug Monitoring Table

Drug	Adverse Effects	Monitoring
Isoniazid	Asymptomatic elevation of aminotransferases, clinical hepatitis, fatal hepatitis, peripheral neurotoxicity, CNS effects, lupus-like syndrome, hypersensitivity, monoamine poisoning, diarrhea	LFT monthly in patients who have preexisting liver disease or who develop abnormal liver function that does not require discontinuation of drug; dosage adjustments may be necessary in patients receiving anticonvulsants or warfarin
Rifampin	Cutaneous reactions, GI reactions (nausea, anorexia, abdominal pain), flu-like syndrome, hepatotoxicity, severe immunologic reactions, orange discoloration of bodily fluids (sputum, urine, sweat, tears), drug interactions due to induction of hepatic microsomal enzymes	Liver enzymes and interacting drugs as needed (eg, warfarin)
Rifabutin	Hematologic toxicity, uveitis, GI symptoms, polyarthralgias, hepatotoxicity, pseudojaundice (skin discoloration with normal bilirubin), rash, flu-like syndrome, orange discoloration of bodily fluids (sputum, urine, sweat, tears)	Drug interactions are less problematic than rifampin
Rifapentine	Similar to those associated with rifampin	Drug interactions are being investigated and are likely similar to rifampin
Pyrazinamide	Hepatotoxicity, GI symptoms (nausea, vomiting), nongouty	Serum uric acid can serve as a surrogate marker for

	polyarthralgia, asymptomatic hyperuricemia, acute gouty arthritis, transient morbilliform rash, dermatitis	adherence; LFTs in patients with underlying liver disease
Ethambutol	Retrobulbar neuritis, peripheral neuritis, cutaneous reactions	Baseline visual acuity testing and testing of color discrimination; monthly testing of visual acuity and color discrimination in patients taking >15-20 mg/kg, having renal insufficiency, or receiving the drug for >2 months
Streptomycin	Ototoxicity, neurotoxicity, nephrotoxicity	Baseline audiogram, vestibular testing, Romberg's testing, and SCr Monthly assessments of renal function and auditory or vestibular symptoms
Amikacin/kanamycin	Ototoxicity, nephrotoxicity	Baseline audiogram, vestibular testing, Romberg's testing, and SCr; monthly assessments of renal function and auditory or vestibular symptoms
Capreomycin	Nephrotoxicity, ototoxicity	Baseline audiogram, vestibular testing, Romberg's testing, and SCr Monthly assessments of renal function and auditory or vestibular symptoms Baseline and monthly serum K^+ and Mg^{2+}
p-Aminosalicylic acid	Hepatotoxicity, GI distress, malabsorption syndrome, hypothyroidism, coagulopathy	Baseline LFTs and TSH TSH every 3 months
Moxifloxacin	GI disturbance, neurologic effects, cutaneous reactions	No specific monitoring recommended
Bedaquililne	GI disturbances, dizziness, headache, rash, arthralgia	Serum K, Ca, MgECG at baseline, weeks 2, 12, 24. Weekly ECG for persons taking other QTc prolonging drugs, history of arrhythmias, hypothyroidism, uncompensated heart failure, or have serum K, Ca, or Mg below normal

LFT, liver function test; SCr, serum creatinine; TSH, thyroid-stimulating hormone.

Data from Nahid P, et al. Executive Summary: Official American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America Clinical Practice Guidelines: Treatment of drug-susceptible tuberculosis. Clin Infect Dis. 1 October 2016;63(7):853–867.

ABBREVIATIONS

AFB	acid-fast bacillus
BCG	bacillus Calmette-Guérin
CDC	Centers for Disease Control and Prevention
CNS	central nervous system
DOT	directly observed treatment
DTH	delayed-type hypersensitivity
HIV	human immunodeficiency virus
IGRA	interferon-γ release assay
IL	interleukin
INF	interferon
LAM	lipoarabinomannan
LTBI	latent tuberculosis infection
MAC	*Mycobacterium avium* complex
MDR	multidrug-resistant
PPD	purified protein derivative
TB	tuberculosis
TDM	therapeutic drug monitoring
TH_1	T-helper type 1
TH_2	T-helper type 2
TNF	tumor necrosis factor
TST	tuberculin skin test
WHO	World Health Organization
XDR	extensively drug-resistant

SELF-ASSESSMENT QUESTIONS

1. A 42-year-old man is receiving treatment for pulmonary TB. He has received 9 weeks of daily rifampin, isoniazid, ethambutol, and pyrazinamide. His sputum smear and cultures have been negative. Susceptibility results have just been made available and indicate the isolate is resistant to isoniazid. Which of the following would be the most appropriate recommendation for your patient at this time?

   A. Discontinue isoniazid, continue rifampin, pyrazinamide, and ethambutol × 6 months.

   B. Discontinue isoniazid, continue rifampin, pyrazinamide, ethambutol, and add levofloxacin × 4 months.

   C. Discontinue isoniazid and ethambutol, continue rifampin and pyrazinamide × 4 months.

   D. Discontinue isoniazid, pyrazinamide and ethambutol, continue rifampin × 4 months.

2. TC is a 74-year-old-man recently diagnosed with multidrug-resistant (MDR)-TB. His physician is thinking about starting a regimen of amikacin, levofloxacin, cycloserine, and *p*-aminosalicylic acid, but is uncertain if this is correct. Therefore, he asks you to evaluate this proposed regimen. You note that his susceptibility tests indicate his organism is susceptible to: amikacin, ethambutol, levofloxacin, cycloserine, and *p*-aminosalicylic acid. His estimated creatinine clearance is 25 mL/min (0.42 mL/s); he has a history of psychosis. From this information, you recommend the following:

   A. Replace the planned cycloserine with ethambutol; make adjustments to amikacin for renal dysfunction.

   B. Continue the planned regimen, but make adjustments to amikacin for renal dysfunction.

   C. Replace *p*-aminosalicylic acid with ethambutol; make adjustments to amikacin for renal dysfunction.

   D. Treat with levofloxacin, cycloserine, and *p*-aminosalicylic acid.

3. Which one of the following patients presenting with cough, fever, and weight loss would be at greatest risk of having TB disease?

   A. Joe who recently travelled to a resort in Cancun, Mexico

   B. Emily who volunteers on holidays at a homeless shelter

   C. Brian who works at a Vietnamese restaurant

   D. Lisa who is on infliximab for rheumatoid arthritis

4. SL has been on antituberculosis treatment for 2 months, which of the following tests would be most appropriate to determine her response to therapy?

   A. Mantoux test

   B. Nucleic acid amplification test

   C. Acid fast baccili (AFB) culture

   D. Interferon Gamma release assay (QuantiFERON®TB Gold)

5. After being discharged from the hospital, LB comes to your pharmacy with prescriptions to continue her antituberculosis regimen. Which of the following drugs would cause pruritus and orange discoloration of her urine, sputum, sweat, and tears?

   A. Isoniazid

   B. Ethambutol

C. Rifampin

D. Pyrazinamide

6. A 68-year-old Asian male with active TB has been on a four-drug antituberculosis medication (rifampin, isoniazid, pyrazinamide, and ethambutol) regimen for 5 weeks. He complains that his right big toe has been painful for 2 weeks, and recently, he has a hard time walking around the house. On examination, the right big toe is tender and red. Laboratory testing shows an elevated uric acid level and gout is suspected. Which of the following antituberculosis medications is most likely associated with this side effect?

A. Isoniazid

B. Pyrazinamide

C. Rifampin

D. Ethambutol

7. An otherwise healthy 29-year-old Asian female with active TB has been improving symptomatically after 6 weeks of antituberculosis medications (rifampin, isoniazid, pyrazinamide, and ethambutol). However, for the past 2 weeks, she has noticed trouble reading phone numbers in the phonebook, and has had trouble reading the newspaper.

On examination, her visual acuity and red/green perception are diminished. The most likely diagnosis is:

A. Ethambutol-associated optic neuritis

B. Isoniazid-induced hepatitis

C. Macular degeneration

D. TB dissemination to her eyes

8. BC is a 36-year-old patient severely immunocompromised with human immunodeficiency virus (HIV) and TB coinfection. Which of the following is the most appropriate treatment approach in this patient?

A. Defer antiretroviral therapy until after TB treatment.

B. Start antiretroviral therapy and then treat start TB treatment 4 weeks later.

C. Start TB therapy and then start antiretroviral therapy as soon as possible after.

D. Start both antiretroviral therapy and TB treatment together, as soon as possible.

9. A 55-year-old emergency room nurse was exposed to TB 4 weeks ago. Susceptibility data are pending for the patient's isolate. Her current purified protein derivative (PPD) was read as 8 mm induration. She has no symptoms and her chest x-ray is normal. Which of the following is the best option in this patient?

A. No treatment needed at this time because the patient is asymptomatic

B. Rifampin daily for 12 months

C. Isoniazid daily for 9 months

D. Rifampin and pyrazinamide for 4 months

10. Which of the following regimens would be the best option for a 26-year-old pregnant female recently diagnosed with active TB?

A. Isoniazid, rifampin, and pyrazinamide

B. Isoniazid, rifampin, and ethambutol

C. Isoniazid, ethambutol, and pyrazinamide

D. Isoniazid, rifampin, and streptomycin

11. A 67-year-old man has received 8 weeks of therapy with rifampin, isoniazid, ethambutol, and pyrazinamide. His sputum was negative for AFB within 2 weeks of initiating therapy. Laboratory tests are drawn and liver function tests are reported as: AST 166 IU/L (8-48 IU/L) and ALT 96 IU/L (7-55 IU/L) (or AST 2.77 μkat/L [0.13-0.80 μkat/L] and ALT 1.60 μkat/L [0.12-0.92 μkat/L]). Which of the following would be the best option for the patient at this time?

    A. Discontinue isoniazid and rifampin and start pyrazinamide, levofloxacin, and ethionamide.

    B. Discontinue isoniazid and rifampin and add moxifloxacin and check serum concentrations of his TB drugs.

    C. Discontinue all TB drugs, continue to recheck liver function tests, and restart same treatment when liver function returns to normal.

    D. Continue current treatment and continue to monitor for continued elevation of liver function tests.

12. A 23-year-old Hispanic male with HIV infection and active TB is receiving highly active antiretroviral therapy and antituberculous treatment with rifabutin, isoniazid, pyrazinamide, and ethambutol by directly observed treatment (DOT). He reports that his right eye has been hurting him for 3 days and is now red. What is the most likely medication for TB, when she has been on four-drug antituberculosis-induced condition?

    A. Ethambutol-induced optic neuritis

    B. Isoniazid-induced peripheral neuropathy

    C. Pyrazinamide-induced acidosis leading to optic neuritis

    D. Rifabutin-related uveitis

13. Which of the following regimens is not an option for treatment of latent TB infection?

    A. Rifampin daily × 4 months

    B. Isoniazid and rifapentine DOT once weekly × 3 months

    C. Isoniazid and rifampin daily for 6 months

    D. Isoniazid DOT twice weekly for 6 months

14. TS is a 58-year-old woman with drug-susceptible TB. She has been on four-drug antituberculosis treatment for 6 weeks and is still smear positive. Which of the following options below would be the most appropriate to do at this time?

    A. Add streptomycin to her regimen and check serum concentrations of her TB drugs.

    B. Continue treatment; *M. tuberculosis* is slow growing and 6 weeks is not enough time to convert to smear-negative.

    C. Inform the patient that her treatment will need to be extended to 12 months.

    D. Continue current treatment and check serum concentrations of her TB drugs.

15. Rifabutin should be chosen over rifapentine or rifampin when a patient is on certain combined antiretroviral combinations because it:

    A. Has a better side effect profile in HIV-positive patients.

    B. Is less likely to induce hepatic clearance of the antiretroviral drugs.

C. It has a lower risk of uveitis.

D. Serum concentration monitoring is available for rifabutin.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** Isoniazid is the only drug that should be discontinued. It is not necessary to add additional agents because smear and cultures are negative and the patient is responding. Therapy should continue with the remaining drugs for at least 6 months.

2. **A.** In patients with creatinine clearance estimated to be less than 30 mL/min (0.5 mL/s), pyrazinamide and ethambutol are recommended to be administered three times per week rather than daily.

3. **D.** While all of these patients would have some increased risk, immunocompromised patients including those on TNF-alpha inhibitors are at high risk for reactivation of latent TB.

4. **C.** Response to therapy and continuation is guided by the sputum and AFB culture results at 2 months and the presence of cavitary disease on chest X-ray at the time of treatment initiation.

5. **C.** Patients on rifampin will typically see orange discoloration of body fluids which may stain clothes and contacts. Other common side effects with rifampin include: pruritus, flu like syndrome, nausea/diarrhea, headache, hematologic effects, and elevated liver function tests.

6. **B.** Pyrazinamide often increases serum uric acid levels. Serum uric acid may be obtained in patients with history of gout especially in the setting of renal insufficiency or with the use of medications which decrease uric acid secretion.

7. **A.** Optic neuropathy is an important side effect of ethambutol that should be monitored especially at higher doses. Patients on ethambutol noting changes in their vision should be referred to an ophthalmologist.

8. **C.** Severely immunocompromised HIV patients with pulmonary tuberculosis should be started on a tuberculosis treatment regimen and antiretroviral treatment should be initiated as soon as possible to reduce the risk of death and risk of immune reconstitution inflammatory syndrome.

9. **C.** The patient was exposed to an active TB patient recently. Her PPD would be considered positive because she was in close contact with an active contagious case in addition to a positive T-Spot test. Since the isolate was resistant to rifamycin, the best option for this patient would be isoniazid for 9 months.

10. **B.** Untreated tuberculosis disease presents a higher risk to the mother and fetus than treatment. The regimen of choice for empiric treatment of presumed drug-susceptible active TB during pregnancy in the United States consists of isoniazid, rifampin, and ethambutol administered for 2 months followed by isoniazid and rifampin for 7 months, for a total of 9 months of therapy

11. **D.** Transient elevations in liver function tests may occur during the first few week of treatment with isoniazid and rifampin. If liver function tests continue to escalate beyond five times the upper limit of normal, discontinuation should be considered.

12. **D.** Cycloserine should be avoided in patients with a history of seizure disorder and used with caution in patients with preexisting mental health issues since it is associated with neuropsychiatric adverse reactions.

13. **C.** Rifampin-based regimens are now preferred as they are shorter in duration and provide excellent tolerability and efficacy. As an alternative regimen, isoniazid can be administered daily for 6 or 9 months as treatment for latent tuberculosis.

14. **D.** Positive sputum cultures after 3 months of antituberculosis therapy requires a review of causes for treatment failure including susceptibility testing and serum concentrations. Additional agents should be added, never add a single drug to a failing regimen.

15. **B.** Rifamycins induce hepatic CYP3A4 enzymes that can accelerate metabolism of protease inhibitors and some nonnucleoside reverse transcriptase inhibitors. Rifabutin is a less potent inducer than rifampin. As rifabutin is also a substrate for CYP3A4 it may require dose adjustments depending on the coadministered drugs.

Chapter 136: Gastrointestinal Infections and Enterotoxigenic Poisonings

Andrew M. Roecker; Brittany N. Bates

KEY CONCEPTS

KEY CONCEPTS

①Infectious diarrhea is a disease that causes significant morbidity and mortality worldwide. Its etiology includes various bacteria, viruses, and protozoans, with viral causes being most predominant globally.

②Two types of infectious diarrhea include watery or enterotoxigenic diarrhea and dysentery or bloody diarrhea. Common pathogens responsible for watery diarrhea are viruses and enterotoxigenic *Escherichia coli*. Common pathogens responsible for dysentery diarrhea are *Shigella* spp., *Campylobacter jejuni*, nontyphoid *Salmonella*, and enterohemorrhagic *E. coli*.

③Fluid and electrolyte replacement is the cornerstone of therapy for diarrheal illnesses. Oral rehydration therapy is preferred in most cases of mild and moderate diarrhea.

④The use of antibacterial therapy for infectious diarrhea is not commonly indicated due to the mild and self-limited nature of the infection, or viral etiology. Antibiotic therapy is recommended in cases of severe diarrhea, moderate-to-severe cases of traveler's diarrhea, most cases of febrile dysenteric diarrhea, and culture-proven bacterial diarrhea in high-risk patients.

⑤Loperamide and diphenoxylate/atropine may offer symptomatic relief in patients with moderate watery diarrhea; however, use of antimotility agents should be avoided in patients with watery and dysentery diarrhea.

⑥Diarrheal illness can be largely prevented by procedures to prevent contaminated food or water supplies and with appropriate personal hygiene.

⑦Oral vancomycin or fidaxomicin are recommended as the initial therapy for patients with *Clostridioides difficile* infection.

⑧Common traveler's diarrheal pathogens include enterotoxigenic *E. coli*, *Shigella* spp., *Campylobacter* spp., *Salmonella* spp., and viruses.

⑨Patient education on prevention strategies and appropriate self-treatment of traveler's diarrhea is preferred, and prophylaxis with antibacterials is not recommended.

⑩Pathogens commonly responsible for food poisoning include *Staphylococcus* spp., *Salmonella* spp., *Shigella* spp., and *Clostridioides* spp.pa

BEYOND THE BOOK

BEYOND THE BOOK

Perform a literature search to identify investigational drugs and therapies for *Clostridioides difficile* infection (CDI) not addressed in the book chapter. Create a document that describes the proposed mechanism of action for each agent.

INTRODUCTION

Gastrointestinal (GI) infections and enterotoxigenic poisonings encompass a wide variety of medical conditions characterized by inflammation of the GI tract. Inflammation-induced vomiting and diarrhea are responsible for much of the morbidity and mortality of these conditions. Diarrhea is defined as a decrease in consistency of bowel movements (ie, unformed stool) and an increase in frequency of stools to three or more per day.[1,2] Acute diarrheal disease is commonly associated with diarrhea lasting less than 7 days, prolonged diarrhea lasts 7 to 13 days, persistent diarrhea lasts 14 to 29 days, and chronic diarrhea lasts 30 days or longer.

This chapter focuses on infectious etiologies of acute GI infections and enterotoxigenic poisonings. A wide variety of viral, bacterial, and parasitic pathogens are responsible for these infections. Chapter e138, “Parasitic Diseases,” discusses the common protozoans that cause gastroenteritis. This chapter will focus on pathogenesis and management of common viral and bacterial etiologies. Because the clinical consequences of dysenteric diarrhea can be more severe compared with cases of watery diarrhea, the chapter is organized accordingly. Epidemiology, clinical presentation, diagnosis, treatment, and prevention strategies are discussed for all GI infections generally, and further elaborated in subsequent sections for specific diseases such as *Clostridioides difficile* infection, traveler’s diarrhea, and foodborne illnesses.

EPIDEMIOLOGY

Dehydration resulting from acute infectious diarrhea is the second leading cause of mortality in children younger than 5 years, killing 525,000 annually.[2] Globally, 1.7 billion cases of infectious diarrhea occur yearly and cause over 1.39 million deaths.[2,3] The incidence of diarrhea for all children younger than age 5 years is 2.9 episodes per child per year. The incidence of diarrhea is higher in younger children, with 4.5 episodes per child per year among children aged 6 to 11 months, compared with 2.3 episodes per child per year among children aged 24 to 59 months.[2,3] Younger children also have a higher risk of death from acute dehydrating diarrhea, and diarrheal disease is still the leading global cause of malnutrition in children younger than 5 years.[2] Although the incidence of childhood diarrhea has been declining, diarrhea remains a major health problem in children, especially in those younger than 1 year.

In the United States, 179 million episodes of acute gastroenteritis occur each year, resulting in nearly 500,000 hospitalizations and more than 5,000 deaths.[4–7] The highest mortality risk from infectious diarrhea in the United States occurs in the elderly, which contrasts to the developing world where the risk of death is highest among young children.[4] Twenty-five percent of all hospitalizations and 85% of all mortality associated with diarrhea involved the elderly (age 60 years and older).[4] In addition to children and the elderly, other groups at risk for GI infections include travelers and campers, patients in chronic care facilities, military personnel stationed abroad, and immunocompromised patients.

ETIOLOGY

① The etiology of GI infections and enterotoxigenic poisonings includes a wide variety of viruses, bacteria, and parasites, although the specific incidence of each is difficult to quantify. Etiologic agents are rarely identified due to the infrequent collection of stool samples, or inability of many laboratories to detect the full range of pathogenic organisms. In this chapter, discussions of pathogens responsible for enterotoxigenic diarrhea focus on viral pathogens (rotavirus and norovirus), enterotoxigenic *Escherichia coli* (ETEC), and cholera. Common pathogens associated with dysenteric diarrhea discussed will be *Shigella* spp., *Salmonella* spp., *Campylobacter* spp., enterohemorrhagic *E. coli* (EHEC), *Yersinia enterocolitica*, and *C. difficile*. Characteristics of watery and dysenteric diarrhea and common pathogens responsible for them are outlined in Table 136-1.

TABLE 136-1

Acute Infectious Diarrhea Clinical Syndromes: Watery Versus Dysentery

	Watery	**Dysentery**
Percentage of patients	90-95	5-10
Stools		
Appearance	Watery	Bloody
Volume	Increased: ++/+++	Increased: +/++
Number per day	<10	>10
Reducing substances	0 to +++	0
pH	5-7.5	6-7.5
Occult blood	Negative	Positive
Fecal polymorphonuclear cells	Absent or few	Many
Mechanisms	• Toxins • Reduced absorption	• Toxins • Mucosal invasion
Complications • Dehydration • Others	• Could be severe • Acidosis, shock, electrolyte imbalance	• Mild • Tenesmus, rectal prolapse, seizures
Etiology	*Vibrio cholerae*	*Shigella* spp.
	Enterotoxigenic *Escherichia coli* (ETEC)	*Salmonella* spp.
	Rotaviruses	*Campylobacter* spp.
	Noroviruses	*Yersinia* spp.
		Enterohemorrhagic *E. coli* (EHEC)
		Clostridioides difficile

Viruses are now the leading global cause of infectious diarrhea. Noroviruses, previously known as Norwalk-like viruses, account for greater than 90% of viral gastroenteritis among all age groups, and 50% of outbreaks worldwide. In the United States, noroviruses have been responsible for about 21% of all acute gastroenteritis cases in young children with outpatient visits, emergency department visits, and annual hospitalizations numbering 627,000, 281,000, and 14,000, respectively.[8] Outbreaks occur throughout the year and have been documented in families, healthcare systems, cruise ships, and college dormitories.

In infants and children, rotavirus, a double-stranded, wheel-shaped, RNA virus, is the most common cause of infectious diarrhea globally, and 1 million people die annually from the infection.[9] In the United States, approximately 3.5 million cases of diarrhea, 500,000 physician visits, 50,000 hospitalizations, and 20 deaths occur each year in children younger than 5 years. Rotavirus is a ubiquitous contagion, infecting the vast majority of children younger than 5 years. After the initial infection, 40% of children are protected against subsequent rotavirus infection, 75% are protected against subsequent gastroenteritis, and up to 88% are protected against severe gastroenteritis. After more extensive vaccination coverage for rotavirus in recent years, hospitalizations from this infection have significantly decreased.[9] Other viral etiologies include astrovirus, enteric adenovirus, pestivirus, coronavirus, and enterovirus. These viruses are increasingly identified as causative etiologies of diarrhea. Characteristics of viral pathogens causing gastroenteritis are outlined in Table 136-2.

TABLE 136-2

Characteristics of Agents Responsible for Acute Viral Gastroenteritis

Virus	Peak Age of Onset	Time of Year	Duration	Mode of Transmission	Common Symptoms
Rotavirus	6 months to 2 years	October to April	3-7 days	Fecal–oral, water, food	Nausea, vomiting, diarrhea, fever, abdominal pain, lactose intolerance
Norovirus	All age groups	Peak in winter	2-3 days	Fecal–oral, food, water, environment	Nausea, vomiting, diarrhea, abdominal cramps, myalgia
Astrovirus	<7 years	Winter	1-4 days	Fecal–oral, water, shellfish	Diarrhea, headache, malaise, nausea
Enteric adenovirus	<2 years	Year-round	7-9 days	Fecal–oral	Diarrhea, respiratory symptoms, vomiting, fever
Pestivirus	<2 years	NR	3 days	NR	Mild
Coronavirus-like particles	<2 years	Fall and early winter	7 days	NR	Respiratory disease
Enterovirus	NR	NR	NR	NR	Mild diarrhea, secondary organ damage

NR, not reported.

② Bacterial causes of acute gastroenteritis in the United States account for more than 5 million cases of diarrhea annually; however, these are vastly underreported and a causative pathogen is identified in less than 3% of cases.[4] FoodNet in 2019 identified 25,866 laboratory confirmed infections, resulting in 6,164 hospitalizations and 122 deaths from these infections.[4,10] Common pathogens responsible for watery diarrhea in the United States are norovirus and ETEC, while those most commonly associated with dysentery diarrhea are *Campylobacter* spp., EHEC, *Salmonella* spp., and *Shigella* spp. Other organisms that are responsible for dysentery include *Aeromonas* spp., noncholera *Vibrio*, and *Y. enterocolitica*. Characteristics of acute bacterial pathogens causing gastroenteritis are summarized in Table 136-3.

TABLE 136-3

Characteristics of Acute Bacterial Gastroenteritis

Bacteria	Incubation Period	Duration	Mode of Transmission	Common Symptoms
Watery Diarrhea				
Vibrio cholerae	2-3 days	1-3 days	Contaminated food or water with human feces usually in areas of inadequate treatment of sewage and drinking water	Profuse watery diarrhea, vomiting, and leg cramps Death can occur within hours without treatment
Enteroaggregative *E. coli*	NR	NR	Contaminated food or water with animal or human feces	Chronic, watery, mucoid, secretory diarrhea with low-grade fever in immunocompromised persons (HIV infections)
Enteroinvasive *E. coli*	10-18 hours	NR	Contaminated food or water with animal or human feces	Watery diarrhea in young children in the developing world
Enteropathogenic *E. coli*	9-12 hours	NR	Contaminated food or water with animal or human feces	Acute onset of profuse watery diarrhea, vomiting, and low-grade fever in young children (<2 years of age) in the developing world
Enterotoxigenic *E. coli*	1-3 days	3-4 days	Contaminated food or water with animal or human feces	Watery diarrhea and abdominal cramping
Dysentery Diarrhea				
Campylobacter jejuni	2-5 days	5-7 days	Contaminated food (particularly poultry), water, or contact with infected animals	Diarrhea (often bloody), cramping, abdominal pain, and fever
Enterohemorrhagic *E. coli*	3-4 days	5-7 days	Contaminated food (particularly cattle) or water with animal or human feces	Severe stomach cramps, diarrhea (often bloody), and vomiting
				Approximately 5%-10% develop hemolytic uremic syndrome
Nontyphoid *Salmonella*	12-36 hours	1-5 days	Contaminated food, water, or contact with infected animals	Diarrhea (sometimes bloody), fever, and abdominal cramps
Shigella	1-3 days	1-7 days	Fecal–oral Contaminated food or water with infected human feces	Watery or bloody diarrhea (8-10 stools/day), severe abdominal pain, fever, and malaise
Yersinia	4-7 days	1-3 weeks	Contaminated food or water	Fever, abdominal pain, and diarrhea (often bloody)

NR, not reported.

Cholera has been rare in the United States because of advanced water and sanitation systems, although slight increases in its incidence have occurred in recent years without clear causes. It is endemic on the Indian subcontinent and sub-Saharan Africa with five countries, Democratic Republic of the Congo, Haiti, Somalia, the United Republic of Tanzania, and Yemen, causing 80% of all cases.[11–13] *Vibrio cholerae* is a gram-negative bacillus sharing similar characteristics with the family Enterobacterales. Cholera is caused by toxigenic *V. cholerae* serogroups O1 or O139. Infections due to *V. cholerae* result in severe and voluminous diarrhea that can quickly result in dehydration. Approximately half of those persons infected with *V. cholerae* O1 are symptomatic, whereas only 1% to 5% of those infected with *V. cholerae* O139 manifest symptoms.[12,13] Vaccination is available to affected areas and to people traveling to those areas that might help in reducing prevalence and severity of disease.[13]

E. coli is a gram-negative bacillus commonly found in the human GI tract, and *E. coli*–associated diarrhea may be differentiated into several distinct categories based on pathogenic features of diarrheal disease: enteroaggregative *E. coli* (EAEC), EHEC, enteroinvasive *E. coli* (EIEC), enteropathogenic *E. coli* (EPEC), and ETEC. ETEC occurs most commonly, and accounts for about half of all cases of *E. coli* diarrhea. There are an estimated 79,000 cases of ETEC in the United States each year.[4] ETEC is also the most common cause of traveler's diarrhea and a common cause of food- and water-associated outbreaks. Infections with EIEC and EPEC are primarily a disease of children in developing countries.[14] EAEC strains are implicated in persistent diarrhea (≥14 days) in human immunodeficiency virus (HIV)-infected patients.[15] EHEC, also known as Shiga toxin–producing *E. coli* (STEC), causes watery diarrhea that becomes bloody in 1 to 5 days in 80% of patients.[14]

EHEC is believed to be the major etiologic factor responsible for the development of hemorrhagic colitis and hemolytic uremic syndrome (HUS). The annual disease burden of STEC in the United States is more than 20,000 infections and as many as 250 deaths; however, the failure of many clinical laboratories to screen for this organism greatly complicates any estimates.[16] In the United States, STEC causes 50% to 60% of all EHEC infections, but in the southern hemisphere, including Argentina, Australia, Chile, and South Africa, non-STEC serotypes are often more prevalent. Non-STEC strains generally produce a lower frequency of dysentery than STEC-positive strains (62% vs 85%).

The *Campylobacter* spp. are flagellated, curved, gram-negative rods. Although there are 14 different species, *Campylobacter jejuni* is the species responsible for more than 99% of *Campylobacter*-associated gastroenteritis. Approximately 2.4 million persons are affected each year in the United States, involving almost 1% of the entire population.[4]

Salmonella enterica is a gram-negative bacilli belonging to the family Enterobacterales. The most prevalent *S. enterica* serotypes are Typhi and Paratyphi, which cause enteric fever. Gastroenteritis is caused by *S. enterica* serotypes Typhimurium or Enteritidis. In the United States, the largest burden of *Salmonella* infection is due to nontyphoidal serotypes, causing approximately 1.4 million cases of salmonellosis, 16,000 hospitalizations, and 600 deaths, occurring annually.[17]

Approximately 165 million cases of shigellosis occur worldwide with 450,000 cases from the United States annually.[18,19] *Shigella* spp. are gram-negative bacilli belonging to the family Enterobacterales. Four species most often associated with disease are *Shigella dysenteriae* type 1, *Shigella flexneri*, *Shigella boydii*, and *Shigella sonnei*.[18,19] *Shigella sonnei* and *S. flexneri* are the most common causes of gastroenteritis in the United States. The other two *Shigella* spp. are more commonly acquired during travel to developing countries. Poor sanitation or personal hygiene, inadequate water supply, malnutrition, and increased population density are associated with an increased risk of *Shigella* gastroenteritis epidemics.

Yersinia spp. are non–lactose-fermenting gram-negative coccobacilli that are widely distributed in nature. The genus *Yersinia* includes six species known to cause disease in humans. *Yersinia enterocolitica* and, to a lesser extent, *Y. pseudotuberculosis* are most likely associated with intestinal infection, but overall both are a relatively infrequent cause of diarrhea and abdominal pain. More than 50 serotypes of *Y. enterocolitica* exist; of these, serotypes 0:3, 0:8, and 0:9 are associated most frequently with enterocolitis.[20] Children are most likely to experience illness with *Y. enterocolitica* infection.

PATHOPHYSIOLOGY

Acute gastroenteritis and its resulting diarrhea are caused by altered movement of ions and water resulting in increased colonic secretion. Under normal conditions, the GI tract has tremendous capacity to absorb fluid and electrolytes, allowing only 100 to 200 mL of fluid to be excreted in the stool daily.[21] The classic enteric pathogen that causes secretary diarrhea is *V. cholerae*, but ETEC and rotavirus also cause watery diarrhea and are much more predominant etiologies in the United States.

V. cholerae is an enteric pathogen that causes classical secretory diarrhea due to changes in ion secretion and absorption. Among the toxins produced by *V. cholerae*, the most important is cholera toxin.[11] Cholera toxin consists of two subunits, A and B. The B subunits are responsible for delivery of the A subunit into the cell. The A subunit stimulates adenylate cyclase, which increases intracellular cyclic adenosine monophosphate (cAMP) and results in protein kinase A–mediated activation of cystic fibrosis transmembrane conductance regulator. This leads to increased chloride secretion and decreased sodium absorption producing the severe watery diarrhea characteristic of the disease.[21] The toxin likely acts along the entire intestinal tract, but most fluid loss occurs in the duodenum. The net effect of the cholera toxin is isotonic fluid secretion early in the intestinal tract that exceeds the absorptive capacity of the latter intestinal tract.
